5.08.1 Introduction

The Dansgaard–Oeschger (D/O) warming and cooling cycles, first described from Greenland ice cores (Dansgaard et al. 1993), are one of the most remarkable and precise pieces of evidence for large-magnitude abrupt climate change, Abrupt climate change is used in this context to mean "abrupt changes in the statistics of important components of the climate system." In their landmark report, National Research Council (2002) provided two definitions: the 'physical' definition: a transition of the climate system from one regime into a distinctly different one, on a timescale that is faster than the responsible forcing. There is also the societal or ecological definition: a climate change that takes place so rapidly and unexpectedly that human and natural systems have difficulty adapting to it during the last glacial period (between 80 and 10 ka). The period of these cycles range from 5 to 10 kyr and are associated with an abrupt temperature increase as large as 20–25 °C (Huber et al. 2006), mostly around the North Atlantic and Western European regions. These temperature changes occurred rapidly within a single decade and lasted for several decades. These cycles are also documented in marine sediment archives. D/O cycles are terminated by Heinrich massive iceberg rafting events with a period of 7.2 kyr from the late Pleistocene Laurentide ice sheet (LIS) (Bond et al. 1993; Rashid and Boyle 2007), mostly over Canada (Hemming et al. 1998). The release of cold freshwater by melting of icebergs is thought to be the link between these rapid temperature increases and abrupt climate change. Introduction of this freshwater to the surface of the North Atlantic is assumed to limit the formation of North Atlantic Deep Water (NADW) in the Norwegian-Greenland seas, and prevented the penetration of the North Atlantic Drift (the northern branch of the Gulf Stream) into higher northeastern latitudes. As a result, the Atlantic meridional overturning circulation (AMOC) is weakened, resulting in the transport of less warm water and a subsequent weaker exchange of moisture from the tropics to high northern latitudes. In contrast, the Gulf Stream transports enormous amounts of heat, maintaining a warmer northwestern Europe, and provides a stronger ocean–atmosphere exchange of moisture during warm stadials when the AMOC is strong.

The impact of these warm–cool D/O cycles was not restricted to the North Atlantic Ocean and the surrounding region; it also extended to the tropical regions, as evident in numerous terrestrial and marine paleoarchives (Clement and Peterson 2008; and references therein). The paleoclimatic records from the northern tropics and subtropics show climate changes concordant with those of the North Atlantic and Greenland, while asynchronous and even negatively correlated phenomena are exhibited in records from the southern tropics and high latitudes of the Southern Hemisphere. For example, the Indian and East Asian monsoon systems appear to positively correlate with the North Atlantic climate, whereas the South American monsoon records show anticorrelation with the Greenland records (Wang et al. 2006). One of the most important effects of the D/O cycles on past climate is their strong spatial variation on the tropical hydrological cycle that caused some parts of the tropics to remain dry while others remained wet. This synthesis provides an overview of the tropical hydrological cycle in the context of abrupt climate change during the last glacial–interglacial cycle. The modern tropical hydrological processes are first discussed followed by a description of a broad tropical paleohydrological cycle perspective during the glacial–interglacial cycle with dynamical underpinning on the African continent, Indian subcontinent, and southeast Asian regions. After exploring the climate scenarios in the modern and glacial perspective, three time slices are discussed at length: the Last Glacial Maximum (LGM; a time window between 24 and 18 ka), the Early Holocene (10–6 ka), and the Late Holocene (5 ka to present) periods. Finally, a perspective on the role of the tropical hydrological changes in modulating ancient civilizations of the Indian subcontinent and NE China is provided.

5.08.2 Modern Tropical Hydrological Cycle

The tropics lie between 30° N and 30° S latitudes, encompassing 50% of the Earth's surface area. Variations occurring here have a tremendous impact on global climate and are associated on an interannual timescale with phenomena such as the Asian monsoon, on a global scale with the El Nino–Southern Oscillation (ENSO), and on millennial timescales with tropical paleoclimate. Home to 70% of the world's 7 population, the region is at the center of the global hydrological cycle and drives the Earth's atmospheric and oceanic circulations and is therefore a fundamental component of global climate dynamics (Cane 1998; Webster et al. 1998; Clift and Plumb 2008). The tropical hydrological cycle describes the continuum of movement of water between the atmosphere, surface, and within the subsurfaces of the earth. The primary components of the hydrological cycle are atmospheric precipitation and terrestrial evaporation. But the distribution of tropical rainfall, hence the tropical hydrological cycle, is not uniform all over the tropics (Chiang 2009); rather, it is centered on specific regions (Figure 1(a)). The atmosphere stores a very small fraction of water relative to the oceans with a significantly shorter residence time, and therefore yields less information regarding past hydrological cycles. Its role as a transport medium is by far more important than its storage capacity, thus imbalances in the hydrological cycle are usually best depicted on land and in the ocean. Paleoclimate records show changes in lake levels, oceans, and discharge from rivers. While the amount of water stored in polar ice sheets (Greenland and Antarctica), high-altitude but low-latitude ice caps, and subsurface layers is enormous, changes in these reservoirs occur on very long timescales and are usually ignored in most discussions of the hydrological cycle. Insolation has varied in the past (Berger and Loutre 1991) and provides the energy driving the hydrological

Figure 1 (a) Tropical climate from a regional perspective. The figure shows July–August climatological rainfall conditions and surface winds (arrows) depicting circulations associated with the Asian (2) and West African (5) monsoons, as well as the subtropical trades flowing into the Intertropical Convergence Zone (ITCZ) regions of the Pacific (2) and Atlantic (4); (5) is the conversion over the Western Pacific Warm Pool. L and H denote locations of relative surface pressure lows and highs. (b) July average (13 years) tropical precipitation (millimeters per hour) from National Aeronautics and Space Administration's (NASA) Tropical Rain Measuring Mission (TRMM) and corresponding ERA Interim reanalysis winds (meters per second) from the European Center for Medium-Range Weather Forecast (ECMWF) for the modern climate (Dee et al. 2011). The scale for the winder vectors is indicated by reference vector (top). Modified after J. C. H. Chiang, 2009: The tropics in paleoclimate. *Annu. Rev. Earth Planet. Sci.* **37**, 263–297.

cycle. The tropics therefore have the capacity to influence the global hydrological cycle on millennial timescales and also provide evidence to study past climate (Cane 1998).

The prevailing view is that warm tropical temperatures primarily enhance sea-surface evaporation, providing the primary input to the atmospheric part of the hydrological cycle. The moisture-laden air is then transported in the rising branches of the Hadley Cell to the extra tropics taking along with it the latent energy absorbed in the tropics. Beyond the Hadley Cell in the extra tropics, transport by transient eddies is significant and can be enhanced during periods of increased meridional temperature gradients between the tropics and the extra tropics (e.g., LGM). Because of the close connection between tropical rainfall and insolation, the temporal variations in tropical rainfall are generally explained by the seasonal migration of the Intertropical Convergence Zone (ITCZ) of the trade winds from an air mass dividing the trade winds from both hemispheres (**Figure 1(b)**). Tropical convection resulting from this convergence tends to concentrate over land masses, the maritime continent of the western Pacific Ocean, and also tropical Africa and South America. Over the Pacific and Atlantic Oceans, northeasterly and southeasterly trades are driven from the high surface pressures in the subtropics toward the low-pressure regions near the equator. Migration of the ITCZ is not uniform over the entire tropics and shows a wide range over East but not West Africa (**Figure 1(b)**), and only a narrow band of rainfall associated with the ITCZ is found in the tropical Pacific in spite of a large oceanic expanse.

The heaviest and most widespread precipitation occurs in the region of the Asian monsoon and does not fit this classic definition involving interhemispheric convergence or migration (**Figure 1**). It is thought that the Qinghai-Tibetan Plateau plays a significant role possibly through topographically induced uplift or convergence of moist air from the Indian Ocean over the Northern Hemisphere summer thermal low that forms over Tibet (**Figure 2**) (Webster et al. 1998; Ratna et al. 2011). Rainfall over the Indian subcontinent and southeast Asia is seasonal but usually associated with a seasonal reversal of winds over the Indian Ocean rather than the convergence of trade winds from the Northern and Southern hemispheres. The thermal low induces a cross-equatorial flow that brings rain-bearing winds into the region. Since coastal monsoon rains act to diminish the sensible heating of the atmosphere (as the heat capacity of the wetted land surface rises), the zone of maximum vertical velocity, and therefore precipitation, will migrate inland to hotter, drier ground. The result is continued pulses of intense rainy periods (active phase) followed by hot, dry conditions (dormant phase) throughout the summer monsoon season, cycling over a roughly 2-week period (**Figure 2**). This precipitation supports nearly a quarter of the Earth's population, hence its significance to civilizations in these regions. More recently, as the underlying mechanisms have come to be better understood, other regions showing an annual climatic cycle with seasonal wind reversals resulting in wet summers and dry winters have also been labeled as monsoonal climates (Webster, 1981; Webster et al. 1998; Rashid et al. 2007). These areas include a large portion of southeast Asia, central Africa, and northern Australia, which are out of phase with the Indian monsoon because of their location in the Southern Hemisphere (Clift and Plumb 2008) (**Figure 1**). A similar but weaker monsoon dynamics exists over West Africa (Chiang 2009). North African precipitation is limited to the southern margins of the Sahara desert, with higher values in the Congo Basin (**Figure 1**). Therefore, variations in lake levels and river discharge provide evidence for past variations in the tropical hydrological cycle in Africa. A precipitation maximum similar to that of Congo is also found over the Amazon Basin in South America. Changes in precipitation across the tropical belt are thought to be linked via the global Walker Circulation. A zonal shift in this circulation can therefore cause drying in one area of the tropics while enhancing precipitation in another and may explain the coherent response from North tropical Africa to East Asia (as discussed in Section 5.08.3). Therefore, while uniform proxies may not be available across the entire tropical belt, changes in precipitation indicated by one proxy in one region can be strongly correlated with other proxies in other regions.

5.08.3 Tropical Paleoclimate during the Last Glacial–Interglacial Cycle

The modern tropical hydrological cycle described earlier weakened during the last glacial–interglacial cycle (including the LGM) (Mix et al. 2001). Oxygen isotopic ratios ($^{18}O/^{16}O$: expressed as $\delta^{18}O$) in ice cores from the Guliya Ice Cap of northwest China (**Figure 3(e)**) show a more negative $\delta^{18}O$ values and are interpreted as a decrease in the amount of moisture being transported in summer during a colder climate. In contrast, less negative $\delta^{18}O$ values are interpreted as a sign of increase, suggesting a stronger moisture transport during warmer conditions. The $\delta^{18}O$ values from the northwestern Tibetan Plateau at an altitude of 6.7 km (above sea level) are higher, suggesting wetter conditions over the Indian Subcontinent, which can be associated with dramatic increases in the strength of the Westerlies (Barnett et al. 2005). Although the $\delta^{18}O$ were generated from a location that is thousands of kilometers away from the North Atlantic realm, records show a remarkable similarity to the Greenland $\delta^{18}O$ records and are postulated to be teleconnected. Data from the Shanbao and Hulu caves in the northeastern Chinese Plain (approximately at sea level) also show a $\delta^{18}O$ pattern similar to that of the Greenland core (Wang et al. 2005). $\delta^{18}O$ in calcite deposits (known as speleothems) show similar high and low values (**Figure 3(b)**) during the D/O cycles for the last glacial–interglacial cycle. This is interpreted as weaker and stronger Asian monsoon, respectively, reflecting a dramatic reduction and intensification of the hydrological cycle in only a matter of decades.

However, the reduction in the hydrological cycle is not uniform on both sides of the equator. Paleohydrological records from South America also show dramatic changes in rainfall, as revealed in speleothem archives. One such highly resolved terrestrial climate record from Caverna Botuvera, southern Brazil is shown in **Figure 2(c)** (Wang et al. 2006). This Southern Hemisphere subtropical site shows high $\delta^{18}O$ values (interpreted as dry periods, weak monsoon, and less rainfall) (**Figure 3(b) and 3(c)**) in sharp contrast to the low $\delta^{18}O$ values of the Shanbao and Hulu caves of northeastern China

Figure 2 Modern Indian monsoon system (Lau and Nath 2012). Output from several simulations based on atmospheric GCMs with spatial resolution in the 25–50 km range, which were compared with available observations of comparable resolution, such as satellite data. Particular attention has been devoted to regional details of the diurnal cycle and fine structure of mesoscale meteorological systems (Lau and Nath 2012). Figure 3 Proxy records that demonstrate abrupt climate changes during the last glacial cycle from various paleoarchives. (a) Global stack of benthic foraminiferal oxygen isotopes ($\delta^{18}O$) (Lisiecki and Raymo 2005) provides chronology of climate events; (b) and (c) $\delta^{18}O$ in the Shanbao and Botuvera speleothems from northeast China and Brazil, respectively (Wang et al. 2006); (d) $\delta^{15}N$ from the Arabian Sea (Atlabet et al. 2002); (e) and (f) $\delta^{18}O$ in the Guliya (NW Tibetan Plateau) and Greenland NGRIP ice cores with revised chronologies (Svensson et al. 2008; Rashid et al. 2011); and (g) June insolation at 65° N (Berger and Loutre 1991). All records are plotted according to their independent age models. Note that the vertical gray bar indicates the duration of Marine Isotope Stage (MIS) 4 (62–74 ka), and the two vertical dashed lines indicate the 20- and 130-ka time horizons.

(interpreted as wet periods and hence intense Asian monsoon and high rainfall) in the Northern Hemisphere. The modern climate of Caverna Botuvera is largely affected by the South American monsoon. When the monsoon dominates during the austral summer season, equatorial trade winds transport moisture from the tropical Atlantic toward the Amazon Basin. Owing to the blocking effect of the Andes, warm and humid air is forced to veer to the southeast, developing deep convection over central and southern Brazil. The antiphased precipitation relationship between eastern China and South America, equivalent tropical regions on either sides of the equator thousands of kilometers apart, reverses during the D/O cycles (**Figure 3(b) and 3(c)**). This antiphasing precipitation dynamics is explained by the north–south shifts in the mean position of the ITCZ and asymmetry in Hadley circulation in both hemispheres. These fluctuations were not associated with seasonal changes as observed today, but with millennial-scale climate shifts. The millennial-scale atmospheric seesaw patterns observed in the Brazilian cave records (**Figure 3(c)**) could have important controls and feedbacks on the climate within hemispheres because of greenhouse properties associated with water vapor (Wang et al. 2006).

Rapid changes in the tropics were also reported from many marine sediment archives, including large fluctuations of biological productivity in surface layers of the ocean. For example, an abrupt fluctuation in the δ^{15} N total organic carbon (TOC) in marine sediments from the Arabian Sea were correlated to the D/O cycles of Greenland (Altabet et al. 2002). The nitrogen isotopes systematics is such that the marine bacteria typical of oxygen-depleted zones preferentially use nitrogen-14 when converting marine nitrates (dissolved NO_3^-) into gaseous nitrogen (N_2O and N_2), leaving the remaining NO_3^- enriched in ^{15}N. Measurements of the $^{15}N/^{14}N$ in organic matter preserved in ocean sediments can thus be used to track changes in the denitrification processes that are usually associated with oxygen depletion in the ocean. It is interesting that the weakening of biological activity in the Arabian Sea fits nicely with the weakening of the Asian monsoon (**Figure 3(d)**). In the global ocean, the abruptness in biological activity could be linked to the injection of nutrients into the surface layer by wind-induced mixing and upwelling. An additional cause could be the direct input of biolimiting elements in dust transported by low-latitude winds. In the Arabian Sea records, a sharp reduction in TOC and low δ^{15}N (**Figure 3(d)**) values were related to the reduction in biological productivity due to the weakening of upwelling along the Somali margin. This reduction in upwelling was tied to the decrease in the pressure gradients due to the potential presence of a larger Qinghai-Tibetan ice sheet and/or the presence of perennial snow cover over Eurasia (Kutzbach 1987).

A fair amount of paleoceanographic data is available from the Arabian Sea to understand the mechanisms behind the origin of the Indian summer monsoon (ISM) and the role of moisture in modulating the continental hydrology. Several studies from both the western (Anderson and Prell 1992) and eastern Arabian Sea show that the ISM has been punctuated by millennial- to submillennial-scale abrupt changes. Using TOC (%) and sonic velocity in three cores from the Oxygen Minimum Zone off Pakistan, Schulz et al. (1998) correlated the variability of the biological productivity to D/O-cycles/H-events. The authors suggested that enhanced biological productivity in the eastern Arabian Sea was forced by the strong summer monsoon. Using dust as a proxy for humidity/aridity, it is suggested that low dust content was associated with a humid continental climate and high dust content was associated with dry conditions in the neighboring Arabian Peninsula.

5.08.4 Tropical Climate during the LGM

The LGM represents a period of the greatest extent and height of ice sheets in both hemispheres during late Pleistocene (Broecker and Denton 1990). In addition, ice caps in the lower latitude but high altitude (such as Kilimanjaro, Qinghai-Tibetan Plateau, South American Cordillera, etc.) were most likely larger, and the snowline descended 1 km lower than their current altitude (Broecker and Denton 1990). These altered physiographic configurations greatly modified the temperature gradients between the polar and subtropical latitudes and intensified atmospheric circulation. Furthermore, the atmosphere was cold and dry, resulting in not only reduction in rainfall but also a change in regional redistribution of rainfall. Most paleoproxies seem to suggest that the tropical terrestrial climate was colder than the tropical sea-surface temperatures (Stute and Talma 1998; Mix et al. 2001).

Paleoproxies for various climate indicators from the tropics were plotted for the period between 10 and 22 ka, including the LGM. Among the greenhouse gases, methane is considered important and is directly related to the tropical hydrological cycle. It is known that the tropics are the main source of atmospheric methane today. However, methane was very low (**Figure 4**) during the height of LGM; this is consistent with cooler tropics, which also have reduced rotting of nutrients and release of methane from lakes, compared to those in polar regions. As described earlier, the Indian and Asian monsoons were also weaker during the LGM (Rashid et al. 2007, 2011) (**Figure 4**) as also the African monsoon (Gasse 2000). Calcium in deep marine sediments mainly reflects the biogenic carbonate component, whereas titanium, which is related to siliciclastic sediment components, varies directly with the terrigenous fraction of the sediment. Therefore, maxima in Ti/Ca ratios characterize periods when precipitation in the Brazilian hinterland abruptly increased and erosion and fluvial transport of terrigenous matter to the shelf and continental slope were strongly enhanced. Clay mineralogic and palynologic studies from nearby marine sediment core sites, as well as speleothem and travertine deposits, confirm the occurrence of more humid phases in northeast Brazil (Wang et al. 2006). It is noteworthy that the Ti/Ca ratios suggest an apparent increase in Amazon runoff (**Figure 4(b)**).

5.08.4.1 Lake Level Records

Water levels in closed-basin lakes have been shown (Gasse 2000) to be a meaningful indicator of the precipitation–evaporation balance in the hydrological cycle and hence an indicator of the state of the hydrological cycle during a given climate epoch. To demonstrate the status of the tropical hydrological cycle in the context of LGM, a 30-ka chronology of lake levels from equatorial Africa has been used in **Figures 5 and 6** (Street and Grove 1979; Gasse 2000). A majority of the lakes showed arid conditions beginning ~22 ka, which intensified after the LGM and reached maximum aridity between 15 and 12.5 ka (**Figure 6**). Although the increases in summer insolation have been invoked as the probable cause, a water balance calculation for eastern Africa implied that a reduction in precipitation of 9–40% relative to today was experienced (Dalfes et al. 1997). Wetter conditions arrived shortly thereafter, and 97% of tropical African lakes abruptly reached their maximum levels in the period from 9 to 7 ka. Relict sand dunes across present subtropical deserts of Africa and Asia from the time of LGM show the onset of wetter conditions beginning around 12–10 ka (Kutzbach 1987). In addition, a gradual migration of a 'belt' of high water levels from about 20° N to 30° N over roughly the 2000 years has been cited and attributed to a poleward migration of the ITCZ. Beginning at 4.5 ka, lake levels again dropped rapidly (as discussed later) and have remained at intermediate to low levels since.

A river's flood- and low-stage levels are useful indicators of local climatic conditions. The Nile River has received a lot of attention, resulting in a significant body of literature about its paleohydrological conditions. An approximate precipitation history has been reconstructed from its water levels (**Figure 6**). At present, the Nile River receives a significant component of its discharge from headwaters in the highlands of Ethiopia. Rainfall in this region is currently dominated by the African–Indian monsoon system. From 20–12.5 ka, the Nile River was braided and highly seasonal, indicating drier conditions (Kutzbach 1987), consistent with the other paleoclimate records from the surrounding region. Between 12 and 5 ka, high water marks in Egypt indicate stronger North African monsoons for the period, followed by potential weakening starting around 4 ka.

Two paleohydrological proxy records from the high altitude tropics of Central Asia (38° N), recording, total particles, sulfate fluxes, δ^{18}O proxies of Dunde ice cores (5.3 km above sea level),

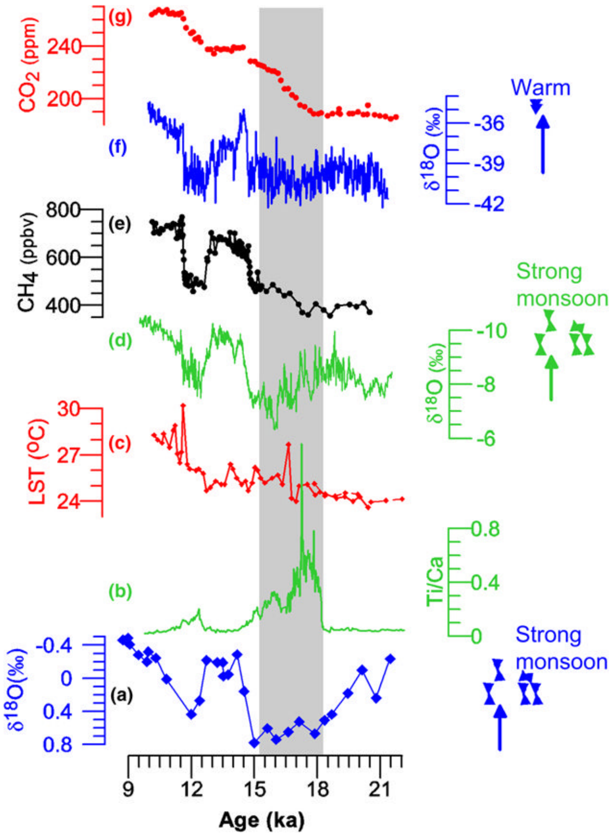

Figure 4 Paleoclimatic proxy records of the last deglaciation. (a) Seawater oxygen isotopes derived from paired Mg/Ca and δ^{18}O measurement of the surface living foraminifera *Globigerinoides ruber* (Rashid et al. 2011); (b) Ti/Ca ratios in bulk sediment from western equatorial Atlantic, interpreted as a proxy for high Amazon River runoff (Jaeschke et al. 2007); (c) TEX$_{86}$-derived surface temperature of Lake Tanganyika; (d) δ^{18}O in Shanbao speleothems (Wang et al. 2005); (e) atmospheric methane concentration (Chappellaz et al. 1997); (f) Greenland Ice Sheet Project 2 (GISP2) methane and oxygen isotope ratios (δ^{18}O) (Blunier and Brook 2001); and (g) atmospheric CO$_2$ from Antarctic Dome C (Monnin et al. 2001) placed on the GISP2 timescale. All records are plotted according to their independent age models.

Res.* **12**, 83–118; Gasse, F., 2000: Hydrological changes in the African tropics since the Last Glacial Maximum. *Quat. Sci. Rev.* **19**, 189–211.

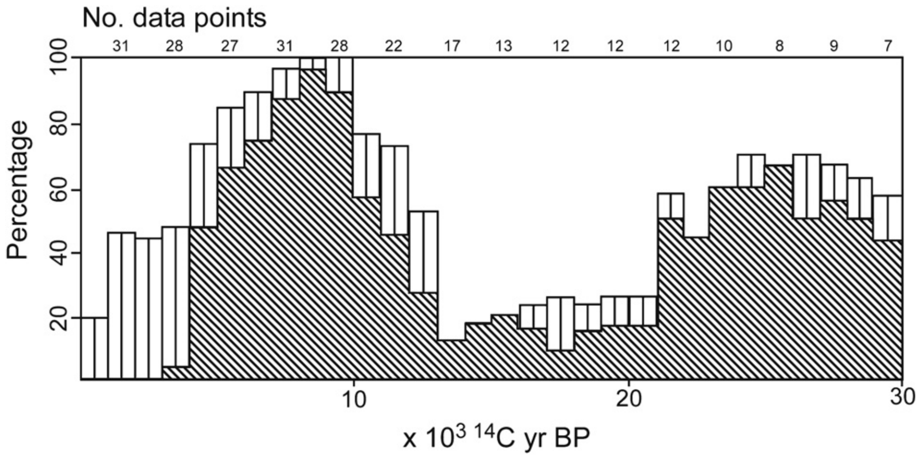

Figure 6 Lake level status for the intertropical African region during the past 30 ka. Street, F. A. and A. T. Grove, 1979: Global maps of lake-level fluctuations since 30,000 yr. *B. P. Quat. Res.* **12**, 83–118; Gasse, F., 2000: Hydrological changes in the African tropics since the Last Glacial Maximum. *Quat. Sci. Rev.* **19**, 189–211.

and lake levels of Africa indicate significant changes in the climate (Figure 7). It is noteworthy that the increased intensity of the African–Indian monsoon (high lake levels) during the early Holocene (11–8 ka) is positively correlated to less dusty and windy climate of the Qaidam Basin of northcentral China (Figure 7). The accumulation rate of ice, as inferred from the sulfate aerosol flux in the Dunde ice cap just northeast of the Qaidam Basin (Figure 7), also shows an inverse relationship between the South Asian and African monsoon records between 10 ka and present (Thompson et al. 1989). Low sulfate concentrations are correlated with high water stands, as this would in effect reduce the area of exposed desiccated sulfate-rich beds in the Qaidam Basin. δ^{18}O and particulate flux records from the same ice core show that the regional climate preceding the Holocene transition (before 12 ka) was colder and windier than it is at present. It is noteworthy that the pattern of low African lake levels between 14 and 21 ^{14}C-kyr are tied to high-altitude but low latitude dry and windy climate as inferred from high dust, low sulfate and more negative δ^{18}O values extracted from the Dunde ice-cap (Figure 7). These records suggest that a sharper (than modern) temperature gradient and ice boundary conditions were present during the LGM, which strengthened and pushed the polar front further south, leading to increased frontal precipitation in the midlatitudes, despite the colder temperatures. However, the anticorrelation between the Dunde ice core records (which seems to suggest a dry and windy climate over the Qaidam Basin) and high African lake level (inferring a wetter and humid climate between 22 and 30 ^{14}C-ky) is not clearly understood. One of the possibilities could be a mismatch between the age models where the former records need to be retuned. Another possibility

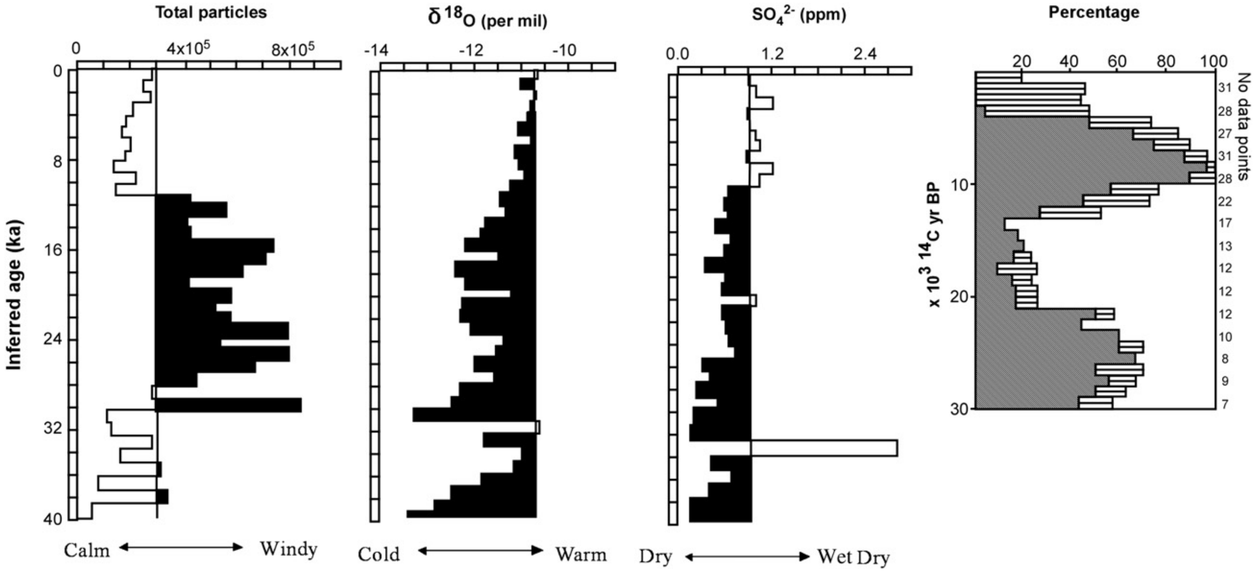

Figure 7 Downcore plots of total particles flux, δ^{18}O, and sulfate flux (parts per million) from the Dunde ice cap (Thompson et al. 1989) and African lake levels (Street and Grove 1979). Reproduced from Thompson, L. G., et al. 1989: Holocene Late Pleistocene climatic ice core records from Qinghai-Tibetan Plateau. *Science*, 246, 474–477.

is that the geographic configuration of the Qinghai-Tibetan ice sheet was different between 22 and 30 ^{14}C-ky in comparison to the LGM, hence influencing the regional climate of the Qaidam Basin. The latter possibility needs to be tested through modeling studies.

5.08.4.2 Marine Sediment Records

A large body of paleoclimatic records is available from the Somali margin of the western Arabian Sea and Arabian Sea in general, as discussed earlier. Here, the correlation of the eastern African climate with that of the Arabian Sea is discussed. Because the southwest winds of the ISM commonly pass over East Africa before turning eastward across the Arabian Sea, various pollen species characteristic of their climate regime are incorporated into the ocean bottom sediments. The percentage of pollen from distant source regions is also a proxy for the strength of the monsoon winds across this region, and most likely over the west coast of India. During the LGM, the pollen data show moderate–high values of steppe and Sahelian species and low humid tropical counts (van Campo et al. 1982). Between 12.5 ka and the climatic optimum (around 8 ka), as the humid tropical species increased toward their highest percentages, a short-term reversal of the trend exists corresponding to 11–10 ka, reflecting a brief period of a cold and dry climate. This latter event is now commonly known as the Younger Dryas (**Figure 3**), which has been reported from many tropical paleoarchives (Thompson 2011). From this point, both the Sudanese savanna and the African montane pollen show steady increases until 8 ka, indicating increased moisture and intensified long-distance transport, respectively.

Several processes related to monsoon strength in the African–Indian region create proxy signals in ocean sediment cores (Clemens et al. 1991; Gupta et al. 2005). Upwelling of cold and nutrient-rich waters (almost equal to high productivity) along the western Arabian Sea is induced by strong southwest monsoon winds. Strong winds also aid aeolian transport of lithogenic sediment from the Arabian Desert to the Arabian Sea. For example, deposition of 70% of the biological and 80% of the lithogenic sediments in the northwest Arabian Sea occurs during summer monsoons. Therefore, sediment cores can preserve monsoon signals (both the strength and timing). In addition, sea-surface temperature (SST) estimates from sediment cores (via foraminiferal census) in the southern subtropical Indian Ocean can be used as a proxy for latent heat availability (as cross-equatorial moisture transport provides 70% of latent heat for summer monsoons; Webster et al. 1998) to the Qinghai-Tibetan Plateau. SST values are anticorrelated with strong summer monsoons since high evaporation rates transferring latent heat to the atmosphere act to cool sea-surface waters (Bard et al. 1997).

5.08.5 Holocene Climate

It has been a common and prevailing view, based mostly on the Greenland ice-core δ^{18}O records, that the Holocene was rather uniform and remarkably stable in comparison to the preceding stadial and interstadial climate (MIS 2–3). However, it appears that the tropical Holocene climate variability may have been greater than has been assumed as more tropical paleoclimatic records emerge from high-elevation ice cores (Thompson 2011), lake sediments (Gasse 2000), cave deposits (Wang et al. 2005), and marine sediment records (Rashid et al. 2011; and references therein). One of the most striking illustrations of such climate variability is the drying of most of the North African lakes. This drying is commonly dubbed the demise of the African Humid Period (AHP) (de Menocal 2001; Adkins et al. 2006), a time when most of the North African region was dotted with numerous lakes, which have since dried out partially or completely disappeared. The transition from a wetter AHP to dry and desert conditions occurred between 6 and 5 ka (depending on the longitude). It is not possible to provide an exhaustive list of all the lake records and their paleoclimate history (Gasse 2000); however, a few lake records have been plotted with other proxy records of climate in **Figures 8 and 9**.

Although precise chronology of these lake records are rare because of lack of dating materials, changes in water levels of four tropical and North African lakes are shown in **Figure 8** for the Holocene. A general trend toward high lake level appears between 10 and 5 ka and then drops to present low lake levels. The high lake levels were punctuated by three short-duration dry events at 12, 8.4, and 6.8 ka, which may correlate to the

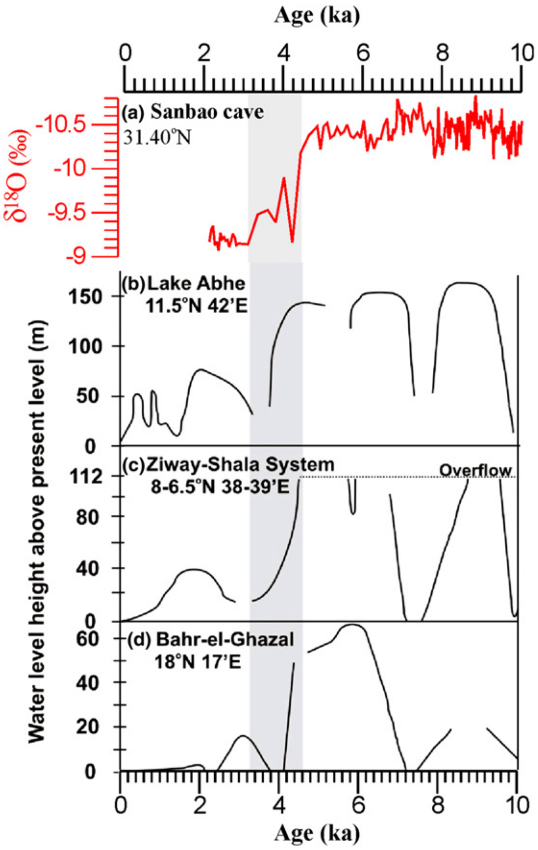

Figure 8 Oxygen isotopes (δ^{18}O) from Shanbao speleothems in northeastern China (Wang et al. 2008) (a) and lake levels from Lakes Abhé of Ethiopia-Djibouti (b), Ziway-Shala of the main Ethiopian Rift (c), and Bahr-el-Ghazal of western South Sudan (d) (Street and Grove 1979; Gasse 2000) are plotted versus age (ka). Note the vertical gray bar highlights the wet to dry climate transition.

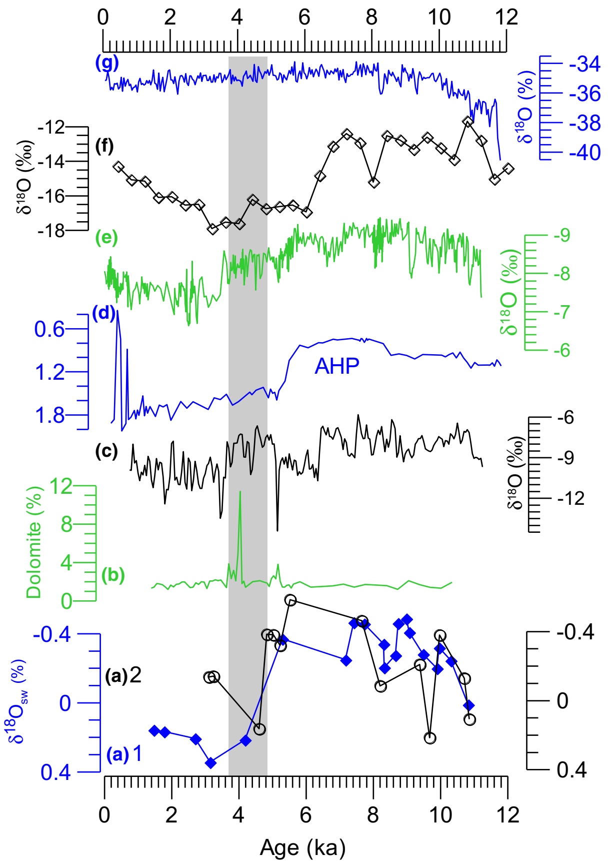

Figure 9 Holocene climate records from the greater Asian region are plotted in comparison with Greenland, Tibetan, and Kilimanjaro ice-core data according to their independent age models. (a1–a2) Andaman Sea (Rashid et al. 2007) and Bay of Bengal seawater $\delta^{18}O$ values (Rashid et al. 2011); (b) Gulf of Oman dolomite concentration (Cullen et al. 2000); (c) Kilimanjaro ice core (NIF3) $\delta^{18}O_{ice}$ (Thompson 2011); (d) African dust flux (de Menocal 2001); (e) $\delta^{18}O$ records from Chinese (Dongge) cave (Wang et al. 2005), (f) Tibetan (Guliya) ice core, and (g) Greenland ice cores. The gray bar shows the major climate transition between 5 and 4 ka. Note: *Y*-axis representing African dust flux (d) is reversed. AHP: African Humid Period.

North Atlantic ice-rafting events of the Holocene (Bond et al. 2001). In addition, there are also fluctuations in the water level of Lake Abhé of Ethiopia-Djibouti (at 11.5° N; Gasse 1977), which rose to a maximum of 150 m, whereas Lake Bosumtwi of Ghana (6.30° N; Talbot et al. 1984) overflowed above 50 m. This difference in lake levels may be due to the amount of rainfall or the constriction imposed by the physiographic framework (smaller versus larger lake size). High water marks of the Nile River in Egypt suggest stronger monsoon for the same period as well, followed by potentially much weaker monsoon starting around 4 ka. The presence of sapropels (black, organic-rich muds) in the Mediterranean Sea corresponding to this period (12–8 ka) are the likely result of large freshwater pulses from the monsoon-fed Nile River (Figure 8). In addition to the lake levels, increases in freshwater discharge have also been identified for the Niger and Senegal Rivers for the early Holocene period (Weldeab et al. 2007), which are consistent with wetter tropics during the early Holocene.

During the late Holocene (5 ka to present), a reduction in rainfall and dry climate conditions is demonstrated in the tropics by dry lake beds or low lake levels and desert conditions spanning a significant portion of West Africa to northeast China (Gasse 2000). The two most dominant climate events, namely, the 5.2- and 4.2-ka events, are nested within this period and are often discussed in the context of demise or abandonment of civilizations. The 5.2-ka event is preserved in diverse paleoclimate archives that include ice-core oxygen isotope records from Mount Kilimanjaro and Huascarán in northern Peru (Thompson 2011), methane records from Antarctica and Greenland (Chappellaz et al. 1997; Blunier and Brook 2001), marine sediment records from the Bay of Bengal (Rashid et al. 2011), and deposition of Saharan dust in the South American Andes (Thompson 2011). Other ice-core proxies, including dust and soluble chemical species such as Cl^- and SO_4^{2-}, also show drastic increases associated with the 5.2-ka event (Thompson 2011).

Terrestrial records, such as trees preserved in a standing position hundreds of feet below the surface of Lake Tahoe (Lindstrom 1990), suggest a wetter climate in the southwest region of the United States. Emerging plants from the retreating margins of an Andean glacier (Thompson 2011) and the 'Tyrolean ice man' or 'Özti' (Baroni and Orombelli 1996) in the eastern Alps are other notable observations concomitant with the 5.2-ka event.

The most widely recognized and widespread abrupt climate event of the late Holocene is dated between 4.5 and 4 ka and is found in many tropical and extratropical paleoclimate archives. It is associated with prominent dust peaks in the tropical ice cores, low lake levels (Dalfes et al. 1997; Gasse 2000) (Figure 9), and weakening of the Indian and Asian monsoons, and is interpreted as a major dry interval during the late Holocene. Marine sediment records from the Gulf of Oman (Kerr 1998; Cullen et al. 2000) and Bay of Bengal (Rashid et al. 2011), as well as lake records from the Gharwal Himalayas and northern Africa, also indicate dry climatic conditions around 4.2 ka. These events are also expressed in archeological data from the Euphrates and Tigris drainage basins. Similar to the 5.2-ka event, it is also believed to have lasted at least a few centuries. This event was related to profound changes in the hydrological cycle in the tropics and midlatitudes and appears to correlate with the decline of past civilizations (Weiss et al. 1993; Rashid et al. 2011).

5.08.6 Past Civilizations and Tropical Hydrological Cycle

Modern tropical hydrological processes influence the distribution of water resources and present-day population density distributions. It is not difficult to see how tropical paleohydrology would have constrained past civilizations that lacked the technical capacity of modern society. At present, nearly 55% of the world's population is found in areas of the globe that receive the highest amounts of rainfall. Almost one-quarter of humanity lives in the Ganga–Brahmaputra–Meghna and Yangtze/Yellow River valleys alone and are directly affected by the twin influences of the Indian–Asian monsoon and the great rivers flowing from the Qinghai-Tibetan Plateau and southern Himalayas. No other region of the world has such a close relationship between humankind and the hydrological cycle than the tropics. Climate studies have shown that the strength of the Indian–Asian monsoon has varied over many timescales, driven by different processes ranging from the gradual uplift of the Qinghai-Tibetan Plateau to the annual cyclicity of ENSO (Clift and Plumb 2008). As the monsoon has varied through time, it has also impacted the lives of people who depend on regular and adequate rains for agriculture. It is therefore not surprising that the onset of drying periods between 4.5 and 4 ka (**Figure 9**) (discussed earlier) coincides with the abrupt end of many civilizations, including the Fourth Dynasty in Egypt (Dalfes et al. 1997). The decline was not limited to tropical Africa but extends to the Harappan civilizations of the Indus River valley (northwest India; Rashid et al. 2011), the Akkadian Empire (Persian Gulf; Kerr 1998) and northeast Chinese civilizations (Rapp and Jing 2011).

An earlier Vedic civilization, which flourished along the banks of the Sarasvati River, has also recently been identified based on fossils of elephants and bamboo curtains (Paliwal 2011). Quaternary gypsum deposits of Rajasthan suggest the existence of an advanced civilization earlier than 12.8 ka, making this civilization older than the Harappan and Mohenjo-Daro civilizations (5 ka) of the Indus Valley (Weiss et al. 1993; Rashid et al. 2011) and northeast China (Rapp and Jing 2011). Abrupt climate events during the Holocene, recorded in a series of lake records and groundwater data from the western Indian peninsula in combination with neotectonic activity, altered the drainage pattern that caused a disappearance of the Vedic Sarasvati River and other tributaries of the Indus River and may have led to the demise of this civilization as well. However, lack of high-resolution radiocarbon dates prevents correlation of these terrestrial records to ISM records (Rashid et al. 2011), which is essential to evaluate the impact of climate change on the fate of ancient civilizations. The second period of drought at 3.2 ka lends support for the hypothesized hydrological link between tropical areas in southeast Asia and North Africa and the resulting effects on civilizations through tropical rainfall.

5.08.7 Concluding Remarks

1. A large number of paleoclimate records show that the tropical hydrological cycle was strengthened and weakened in tandem with the D/O warming and cooling cycles as recorded in the oxygen isotopic ratios of Greenland ice cores. The weakening and strengthening of the hydrological cycles were tied to the shift in the mean position of the intertropical convergence zone to a more southern latitude than its position under the modern climate configuration.
2. The LGM (18–24 ka) is characterized in all of the tropical records as a period of generally dry and windy climate. A majority of paleolake level data from Africa, marine sediment records from the Arabian Sea and Bay of Bengal, and South Asian speleothem oxygen isotopic data suggest that the African–Indian–Asian monsoons were weaker during this time. As a result, biological activity off the coast of Oman margin was weaker and the outflow from the Indian subcontinent rivers was low compared to modern outflow. Orographic influence of the greatest polar ice sheets coupled with a potentially larger Tibetan Plateau ice sheet, larger sea-ice extent in the North Atlantic Ocean, and perennial Eurasian snow cover likely played a wider role in limiting the inland propagation of the Indian–Asian monsoon. This altered configuration deprived the North African region from adequate rainfall, resulting in the drying of numerous lakes.
3. The early Holocene climatic optimum period (ranging from 10.5 to 6 ka) is recoded in varying degrees and durations, but is present in virtually all records, indicating overflow of many African lakes, stronger Indian–Asian monsoon, and associated higher rainfall. A northward migration of the mean position of ITCZ is the most plausible explanation for the lag in maximum lake level stands recorded at the most northerly tropical regions. There exists a significant amount of evidence to support widespread drought conditions beginning about 4.5 ka, with only moderate recovery to present. In addition, as evidenced by the desiccation of lakes in northwest India and parts of North Africa, the northernmost extent of monsoon rains retreated and has not since returned to this region.
4. The onset of a late Holocene drought period coincides with the demise of many ancient civilizations surrounding the North African region, northwest India, and northeast China. It is beyond the scope of this chapter to describe the archeological evidence that seems to negate connections between the demise of past civilizations and changes in the amount of rainfall. However, the authors suggest a tentative link between the two, which might provide fodder for further research. During the late Holocene, there were likely several hundred million people on the planet with only a fraction subjected to this acute hydrological condition. The impact of such a rapid and sustained drought event today with 7 billion people would be devastating and thus requires attention.

In the last three decades, we have witnessed many events that underscore an inherent risk that humans face today should a similar drought event were to occur. It is therefore urgent that society develops a much better understanding of what caused these events, their consequences, and, potentially increase their predictability (Rial et al. 2004). It is clear that the paleoclimate community has uncovered information about Earth's natural climate behavior that is unprecedented in the instrumental record and is not well appreciated by the broader climate science community. Given the growing concern that Earth may be experiencing another abrupt climate change today, these past episodes of abrupt climate change provide us an opportunity to study how the climate system enters an abrupt change by developing the necessary data that can be coupled with model experiments designed to answer why Earth has experienced such dramatic changes in the recent past. This will shed light to adopt a bottom–up climate vulnerability approach.

5. In the modern climate setting, rain does not fall uniformly across the globe, especially in the tropical regions. The locus of maximum rainfall is located over the monsoon region in Asia where convergence of hemispheric winds is absent,

making the ITCZ a secondary factor. Even in other regions showing strong links to the seasonal migration of the ITCZ, the range of migration is not uniform. In spite of these variations, modern climate is known to have a global Walker Circulation capable of coordinating tropical hydrology. The coherence in paleoclimate records suggests that such circulations may have been present during the periods discussed here.

5.09.1 Introduction

Arid and semiarid regions constitute approximately 25% of the contiguous United States and a significant fraction of the world. Understanding and management of water resources entail reliable and timely data sets, analytical tools, and representative models. In arid and semiarid regions, available water resources are often very sensitive to seasonal to interdecadal climate variability. Therefore, reliable quantitative estimates of the components of the hydrologic cycle are fundamental to water resources management and risk assessment. In particular, precipitation is one of the key variables that plays a significant role in the hydrologic cycle.

Accounting for climate variability and population growth is fundamental to vulnerability assessment of water resources system. For example, studies have highlighted that water resources and flood risks are sensitive to climate change and thus, watershed management and planning strategies should be adjusted accordingly (Stoll et al. 2011; Sivakumar 2011, among others). These sensitivities are particularly high in the western United States (Reclamation 2011; Seager et al. 2007; Schlenker et al. 2007; Cayan et al. 2008).

Western United States can expect multiyear periods of drought followed by unusually wet winters along the West Coast (often in phase with the El Nino Southern Oscillation), shifts in the timing of wet and dry periods, and increases in summer monsoonal moisture. On the other hand, population of Arizona, Southern California, and Southern Nevada are projected to increase in a 30-year period (1990–2020) by 90, 57, and 104%, respectively (Morrison et al. 1996). This stands to not only increase in water stress in southwestern United States, but height flood risks through land cover changes associated with expanding urban areas.

In recent years, Intergovernmental Panel on Climate Change (IPCC) reports (e.g., IPCC 2007) attempted to assess potential climate change and variability impacts on the water cycle and precipitation, among other variables. While IPCC reports provide valuable information to the climate community, the resolution is too coarse for engineering and decision-making applications, which require high resolution and local information (Pielke et al. 2011; Solomon et al. 2007).

Improving our understanding of the water cycle, along with the development of reliable high-resolution precipitation data sets, is essential for monitoring and predicting water resources. Currently, rain gauge measurements and radar data provide the main inputs for water resources management and hydrologic forecasting (e.g., streamflow simulation, flash flood warnings, drought monitoring, and weather watches) across the United States. Poor spatial sampling and uneven distribution are the main limitations of rain gauges. Obviously, these limitations often make the data inadequate to support water resources studies, particularly over large scales. Given the high variability of precipitation in space and time (Corradini and Singh 1985; Troutman 1983), most parts of the globe lack sufficient number of rain gauges to capture precipitation accurately.

Weather radar systems provide valuable and detailed information on precipitation. However, in most parts of the globe, radar networks are not available. Even in the United States, which is equipped with state-of-the-art radar systems, there are regions with extensive topographic relief that suffer from poor radar coverage (e.g., western United States; Maddox et al. 2002). For example, Maddox et al. 2002 demonstrated that in the western United States, at 1000 m above ground level, the radar coverage area is substantially less than 3000 m above ground level (Figure 1).

Evidently, lack or absence of in-site and radar installations hamper the development and use of water resources management and decision-making model. Therefore, alternative methods of precipitation estimation with sufficient sampling density and reliability are necessary for operational applications.

Satellite-based precipitation data sets have the potential to improve precipitation observation at a quasi-global to even global scale. In the past three decades, the National Aeronautics and Space Administration (NASA), National Oceanic and Atmospheric Administration (NOAA), and many other international agencies have sponsored satellite missions to improve precipitation estimation. Thus far, many algorithms have been developed to retrieve precipitation in near real-time (e.g., Tropical Rainfall Measuring Mission (TRMM) 3B42, Huffman et al. 2007; CPC Morphing Technique (CMORPH), Joyce et al. 2004; and Precipitation Estimation from Remotely Sensed Information using Artificial Neural Networks (PERSIANN), Sorooshian et al. 2000, Hsu et al. 1997).

It is well known that satellite-retrieved data sets have several advantages over rain gauge measurements (e.g., higher spatial

http://dx.doi.org/10.1016/B978-0-12-384703-4.00512-8

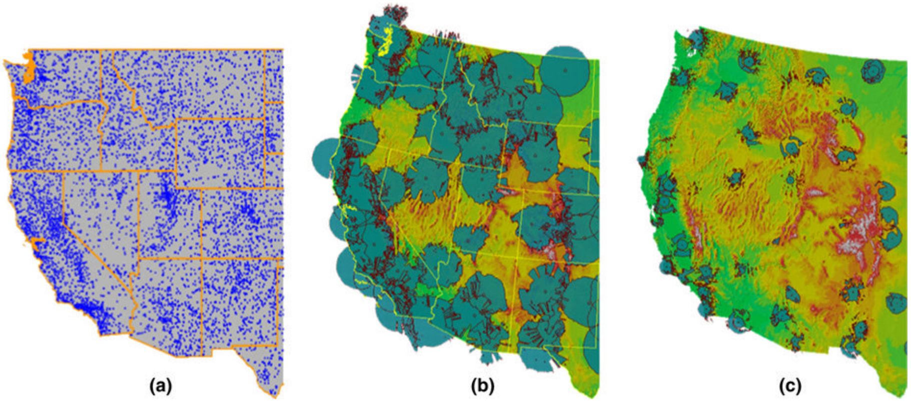

Figure 1 (a) Rain gauges (NCDC data); (b) radar coverage 3000 m above the ground level; (c) radar coverage 1000 m above ground level. After Maddox, R., J. Zhang, J. Gourley, and K. Howard, 2002: Weather radar coverage over the contiguous United States. *Weather Forecast.*, **17**, 927–934.

resolution and uninterrupted measurement). However, satellite precipitation products have not yet fully integrated into water resources engineering and management models, mainly because of (1) the relatively short length of the data record for climatological studies, (2) retrieval errors due to the indirect nature of satellite observations, (3) the undetermined uncertainties and error bounds, and (4) a general lack of experience in the utilization of satellite data for practical applications. In the following, after a brief discussion on remote sensing of precipitation, the potential applications of satellite-based data to drought monitoring, flood forecasting, and water resources management are highlighted. It is hoped that this introduction motivates greater utilization of satellite data in water resources management and decision making.

5.09.2 Remote Sensing of Precipitation

Since the launch of the Television and Infrared Observation Satellite (TIROS-1), the first meteorological instrument, the number of remotely sensed observations has been increasing. Satellites can be categorized into two main groups: (1) low earth orbit (LEO, revisiting the same spot on the Earth at regular intervals) and (2) geostationary (GEO, hovering over the same location on Earth continuously, Kidd 2001).

GEO satellites are placed at altitudes of 35 880 km and move at the speed of the Earth's rotation. GEO satellites are widely used to measure meteorological variables using the visible (VIS) and infrared (IR) wavebands (Levizzani 2008). On the other hand, LEO satellites are positioned in sun-synchronous orbits and thus are able to visit any spot on the Earth at regular intervals. Thus far, passive microwave (PMW) sensors have been installed on LEO satellites. These sensors offer more accurate precipitation estimates than the GEO satellites (Huffman et al. 2007; Hsu et al. 1999). On the other hand, GEO satellites provide more frequent measures of precipitation over the hemispherical disk, which is crucial for hydrologic prediction and real-time monitoring systems.

IR and VIS scans provide frequent (less than 30 min) estimates of cloud-top temperature and albedo that can be used to retrieve precipitation estimates. It is noted that the indirect nature of precipitation estimation from sensors on GEO platforms constitutes considerable uncertainty in precipitation estimates. On the other hand, the PMW sensors aboard LEO satellites offer more direct, and thus more accurate, instantaneous precipitation data. However, LEO satellites visit each spot on Earth only once or twice per day, which may not be sufficient to capture temporal variability of precipitation. The low temporal resolution of LEO satellites can be compensated for by integration of data from GEO sensors in order to obtain better temporal and spatial sampling of diurnal rainfall variability. Verification and validation studies indicate that merging LEO and GEO satellites data exploit the advantages of both types of sensors in precipitation estimation (Xie and Arkin 1997; Turk et al. 2006; Adler et al. 2001; Huffman et al. 1997; Levizzani et al. 2007).

As mentioned earlier, different satellite rainfall-retrieval algorithms have been developed to derive precipitation rates in near real-time (e.g., TRMM Multi-Satellite Precipitation Analysis (TMPA), CMORPH, PERSIANN). A comprehensive review of precipitation algorithms is beyond the scope of this chapter. For reviews and product comparisons, the interested reader is referred to Tian et al. (2009), Adler et al. (2001), Levizzani and Amorati (2002), Tian et al. (2007), and Kidd (2001). In the following, the PERSIANN retrieval algorithm is discussed in more detail. This algorithm uses an artificial neural network (ANN) classification approach to estimate precipitation rates. The original version of the PERSIANN algorithm was based on IR imagery from GEO sensors, while the current operational version is extended to include PMW data from LEO satellites for parameter adjustment and calibration.

The PERSIANN retrieval scheme transforms IR images to precipitation estimates in three steps: (1) extracts the mean and variance of cloud-top brightness temperatures in the vicinity of each pixel; (2) classifies the extracted features (e.g., cloud-top temperature patterns); (3) translates the classified features to precipitation rates. The current operational version of the PERSIANN runs in two parallel modes: (1) 'simulation mode,' which produces precipitation rates at the 0.25° × 0.25° gridded resolution and every 30 min based on the GEO IR data and (2) the 'continuous update mode,' which continuously updates the parameters of the algorithm using PMW-based precipitation data (Hsu et al. 1997). PMW calibration is performed by dividing the PERSIANN coverage overlapping subregions. The

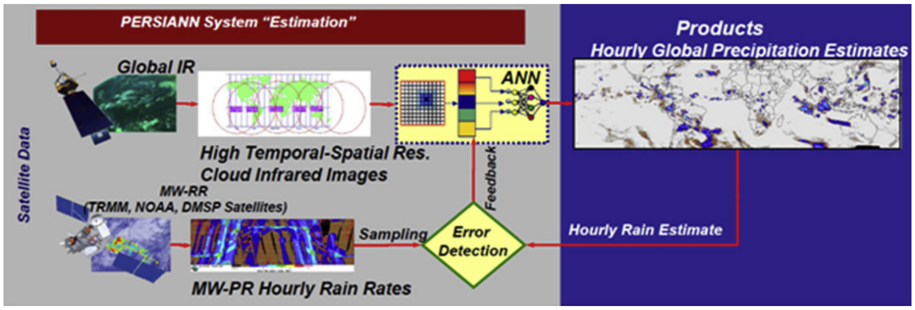

Figure 2 Components of the PERSIANN precipitation algorithm; MW, microwave; PR, precipitation radar. Modified after Hsu, K., H. Moradkhani, and S. Sorooshian, 2009: A sequential Bayesian approach for hydrologic model selection and prediction. *Water Resour. Res.*, **45**, 2038–2059, w00B12. Reproduced from Hsu, K., and S. Sorooshian, 2008: Satellite-based precipitation measurement using persiann system. *Hydrological Modeling and The Water Cycle – Coupling the Atmospheric and Hydrologic Models*, S. Sorooshian, E. Coppola, B. Tomassetti, M. Verdecchia, K. Hsu and G. Visconti, Eds., Springer, 27–48.

simulation mode estimates are then adjusted and calibrated using the instantaneous PMW data that fall within the same subregion. The interested reader is referred to Hsu et al. (1997) for a more detailed discussion on the calibration procedure.

In the simulation mode, the PERSIANN algorithm relies on gridded IR images from multiple satellites such as the East and West Geostationary Operational Environmental Satellites (GOES) and the Geostationary Meteorological Satellite (GMS-5) provided by the NOAA Climate Prediction Center (CPC, see Janowiak et al. (2001) for details). The required PMW-based precipitation data are obtained from the available LEO satellites. It is worth pointing out that GEO data can be obtained at up to 15 min intervals; however, PMW estimates are not available at such a high time resolutions for parameter calibration.

Currently, PERSIANN precipitation estimates cover 60° S to 60° N, with a time interval of 3 h and a spatial resolution of 0.25° since 2000. PERSIANN estimates are then accumulated to various temporal resolutions (e.g., daily) for hydrologic applications. Figure 2 displays the components of the retrieval algorithm.

5.09.3 Application to Water Resources Vulnerability Assessment

5.09.3.1 Drought Monitoring

Droughts are relatively common in arid and semiarid regions. Sensitivity of agriculture and many other industries to drought conditions is well recognized. Therefore, drought monitoring and prediction is of particular importance over arid and semiarid regions. In recent years, satellite data sets are being used for drought analysis. The African Drought Monitor (Sheffield et al. 2006), for example, produces land-surface hydrological conditions. In this model, PERSIANN and TMPA data are used as input, while model outputs include drought conditions and quantitative estimates of water-budget components.

Anderson et al. (2008) investigated droughts based on vegetation response using TMPA precipitation data. The results indicated that higher water deficiencies coincided with critical months in the enhanced vegetation index (EVI). Anderson et al. 2008 concluded that satellite data can be used to investigate drought impacts on vegetation. Paridal et al. (2008) highlighted the potential of satellite precipitation estimates for drought monitoring in a case study across the Philippines. In a recent study, Zhang et al. (2008) demonstrated the application of remote sensing data to drought monitoring based on the plant water stress index (PWSI; Idso et al. 1981).

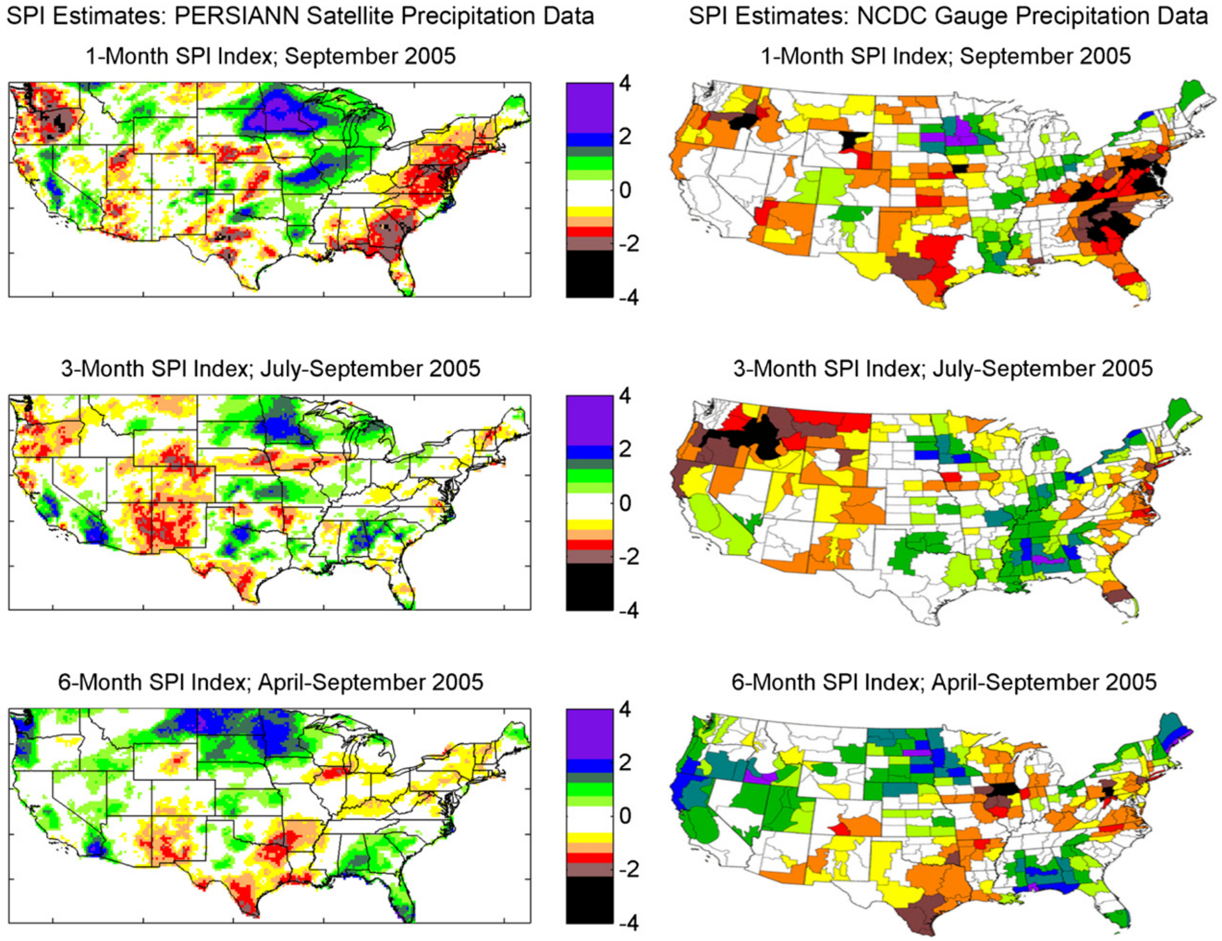
In the following, an example application of PERSIANN satellite data to drought analysis is demonstrated. The standardized precipitation index (SPI) is estimated for each precipitation pixel across the contiguous United States using real-time PERSIANN data and Global Precipitation Climatology Project (GPCP) data (Huffman et al. 1997). In this example, the log-term GPCP data are used to derive the climatology of precipitation, while real-time satellite data are used for drought monitoring. The SPI is employed to identify persistent lack of precipitation at various time scales (e.g., 3, 6, 12, and 24 months). In order to derive SPIs, a gamma distribution is fitted to the precipitation record, and the accumulated gamma distribution is then transferred to a normal cumulative density function (CDF). Consequently, SPI is standardized to a normal distribution having null mean and unit standard deviation (McKee et al. 1993). Table 1 lists the SPI classification of wet and dry conditions.

The SPI describes the amount of precipitation over a certain period in a normalized scale. A high SPI (>2.0) represents high precipitation accumulation, whereas a low SPI (<2.0) refers to precipitation less than the climatological mean over a certain period (e.g., 3-, 6-, and 12-month periods). The SPI indicates normal precipitation accumulation (near climatological mean). In other words, consecutive negative SPI values indicate persistent dry periods or drought conditions (McKee et al. 1993).

Figure 3 displays the SPI values derived using PERSIANN satellite data and GPCP climatology (left panels) and the

Table 1 SPI classification of wet and dry conditions

SPI index	*Climatic condition*
>2	Extremely wet
1.5–2.0	Very wet
1.0–1.5	Moderately wet
−1.0 to 1.0	Near normal
−1.0 to −1.5	Moderate drought
−1.5 to −2.0	Severe drought
<−2.0	Extreme drought



SPI Estimates: PERSIANN Satellite Precipitation Data

SPI Estimates: NCDC Gauge Precipitation Data

1-Month SPI Index; September 2005

3-Month SPI Index; July-September 2005

6-Month SPI Index; April-September 2005

Figure 3 SPI estimates using PERSIANN precipitation data (left panels) and the NCDC Global Historical Climatology Network (GHCN) data set (right panels).

National Climatic Data Center (NCDC) Global Historical Climatology Network (GHCN) gauge data set (right panels). In Figure 3, 1-month (Sep. 2005), 3-month (Jul.–Sep. 2005), and 6-month (Apr.–Sep. 2005) SPI values are presented in the upper, middle, and lower panels, respectively. Note that the NCDC drought analyses are at the climate division scale, as opposed to PERSIANN-based SPI values computed at the pixel scale. One can see that the patterns of wet and dry conditions are quite similar in both left and right panels. The differences between the SPI values are mainly due to the (1) normalization interval (NCDC employs long-term gauge data, while GPCP data are available from 1979) and (2) spatial scale (NCDC analysis are averaged over climate divisions, while satellite-derived SPIs are pixel based). Overall, Figure 3 demonstrates that satellite precipitation data can potentially be integrated into drought monitoring systems, particularly over remote areas where other sources of information may not be available.

For reliable drought analysis, long-term precipitation data sets are of primary importance. NASA's GPCP (Huffman et al. 1997; Adler et al. 2003) and NOAA's CPC Merged Analysis of Precipitation (CMAP, Xie and Arkin 1997) data sets have been providing precipitation data since 1979. On the other hand, the emergence of real-time high-resolution precipitation products provides a unique opportunity to integrate merged satellite data sets into drought monitoring and analysis systems. One of the limitations of the high-resolution satellite data is a relatively short length of record. Currently, long enough records can be obtained only by merging multiple products. Evidently, merging multiple products may lead to some level of inconsistency as products change over time.

The community of satellite precipitation research continuously progresses toward better quality and higher space–time resolutions. In particular, efforts are underway to develop a consistent retrospective precipitation data set back to the early 1980s. Some of the high-resolution precipitation products (e.g., TMPA, CMORPH) rely mainly on more accurate but infrequent LEO data. This restricts their applicability for reconstruction of precipitation records for pre-PMW era (1997). On the contrary, the PERSIANN can be viewed as a two-phase algorithm: (1) the training phase, during which an ANN is trained based on PMW and ground-based observations and (2) the application phase, in which the trained model can be applied to IR-only images. Therefore, the PERSIANN algorithm is uniquely positioned to produce precipitation records prior to 1997 using historical IR observations. In the near future, this approach will provide a long-term high-resolution precipitation data set for weather and climate research and applications. This could bridge the gap between low-resolution long-term data and recent high-resolution precipitation data sets and the need for high-quality long-term data required for drought monitoring.

5.09.3.2 Flood Monitoring/Assessment

Floods are the most life-threatening hydrologic extremes and result in significant loss of lives and property damages. In fact, floods are one of the most common and widespread natural disasters. A 20-year (1985–2004) record shows that on average 150 flood events occurred each year across the globe. These events resulted in 7500 deaths and approximately $15 billion in property and economic damage (Stromberg 2007). The severity and impact of floods depend on several factors such as watershed characteristics, storm type and intensity, antecedent soil moisture, snowmelt, and land use change. Generally, any systematic approach to the simulation of streamflow has three main components: (1) model, (2) parameter estimation and model calibration, and (3) data requirements. It is our view that one of the major challenges in reliable hydrologic forecasting is providing accurate data sets as input to models. This section envisions future improvements that can be achieved by the integration of satellite data to streamflow simulation.

Among the required data sets, precipitation is perhaps the main driving force in streamflow simulation models (Cloke and Pappenberger 2009). Regardless of the choice of model, accurate measurement of extreme precipitation events is fundamental to flood forecasting. Traditionally, rain gauge observations have been the main input for streamflow simulations. However, unrepresentativeness of rain gauges across most of the world is a major limitation to support monitoring and predicting watershed response. As stressed earlier, radar networks are either not available or inadequate for operational applications, except in a few countries. Therefore, there exists the need to obtain alternative measures of precipitation to enable streamflow simulation and forecasting for operational applications.

Figure 4 highlights the importance of satellite data in flood forecasting applications. In the left panel, the gray areas show weather radar coverage in the southwestern United States, and the black areas represent no radar coverage, mainly because of terrain blockage. The right panel displays PERSIANN satellite precipitation estimates. As shown, in this particular event, radars did not detect a large part of the storm (black areas), while satellite estimates captured the entire event. Evidently, missing a large part of the storm would adversely affect the performance of flood forecasting models. In fact, even a sophisticated hydrological model cannot forecast flooding, if the input precipitation is not captured by ground-based observation networks.

Figure 4 Importance of satellite data in flood forecasting applications. In the left panel, the gray areas show weather radar coverage in the southwestern United States. The right panel displays PERSIANN satellite precipitation estimates. As shown, radars did not detect a large part of the storm (black areas) mainly because of terrain blockage, while satellite estimates captured the entire event.

Flash floods, in particular, are very difficult to predict, as they occur in a relatively short time. Flash flood occurrence is affected by the amount of precipitation, antecedent soil moisture, soil type, and topography, among other meteorologic conditions. Among all, the amount of precipitation and its space–time variability are the main factors for reliable flash flood forecasting. Numerous studies have highlighted the significance of spatiotemporal variability of precipitation and its impacts on hydrologic applications (Corradini and Singh 1985; Schuurmans and Bierkens 2007; Fiener and Auerswald 2009; Haile et al. 2009; Fiener and Auerswald 2009).

In this regard, satellite precipitation data sets provide a great opportunity to capture the space–time variability of precipitation, particularly over regions where other means of precipitation measurement are sparse or nonexistent (Tang et al. 2009). However, lack of information on uncertainty of satellite data sets limits their application in operational flood forecasting (AghaKouchak et al. 2011). Despite extensive research, uncertainties of remotely sensed precipitation data have not yet been well quantified (Hossain and Huffman 2008; Margulis et al. 2006; Dong et al. 2005; Hossain and Anagnostou 2005; AghaKouchak et al. 2010a). Quantification and characterization of precipitation uncertainties are important as spatial and temporal variability in input precipitation is one of the main sources of error in rainfall–runoff processes and hydrologic predictions (Schuurmans and Bierkens 2007; Syed et al. 2003; Arnaud et al. 2002).

The quality of satellite data can be improved by merging different sources (multisensor) of data (e.g., gauge and radar) in order to obtain the optimal estimates of precipitation. Since each measurement technique or sensor has its own advantages and disadvantages, integrating multiple sensors may improve the quality of observations. In this regard, an adjusted version of the PERSIANN precipitation data (hereafter referred to as PERSIANN-MBA; monthly bias adjusted) are developed based on the GPCP version 2 (Adler et al. 2003). In this data set, the volumetric bias is removed based on monthly accumulations of the GPCP data. In other words, spatial patterns of precipitation are derived from original PERSIANN data, while the precipitation accumulations are adjusted by GPCP data.

Validation studies show that the PERSIANN-MBA is significantly improved with respect to the unadjusted rainfall estimates. This improvement is crucial for hydrological modeling. Figure 5 displays time series of observed precipitation and simulated streamflow over the Illinois River basin ((a) PERSIANN satellite precipitation data, (b) bias-adjusted satellite data (PERSIANN-MBA), (c) simulated streamflow using data in (a), and (d) simulated streamflow using data in (b)). In panels (a) and (b), the gray lines show the monthly averaged Stage IV radar reference data, whereas in (c) and (d) the gray

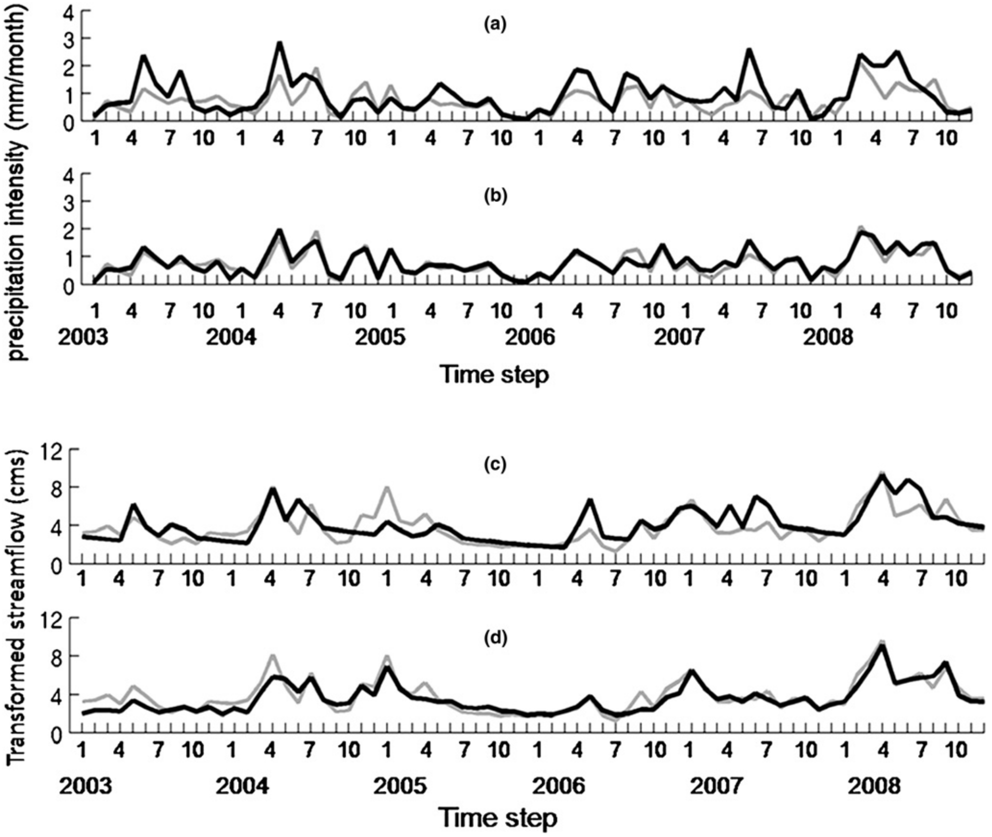

Figure 5 Time series of observed precipitation and simulated streamflow over the Illinois River basin. (a) PERSIANN satellite precipitation data; (b) bias-adjusted satellite data (PERSIANN-MBA); (c) simulated streamflow using data in (a); (d) simulated streamflow using data in (b). In panels (a) and (b), the gray lines show the monthly averaged multisensor radar reference data, whereas in (c) and (d) the gray lines represent monthly averaged observed streamflow (see Behrangi et al. (2011) for more details). Reproduced from Behrangi, A., B. Khakbaz, T. Jaw, A. AghaKouchak, K. Hsu, and S. Sorooshian, 2011: Hydrologic evaluation of satellite precipitation products at basin scale. *J. Hydrol.*, **397**, 225–237.

lines represent the monthly averaged observed streamflow. The simulated streamflows are derived using the Sacramento Soil Moisture Accounting Model (SAC-SMA) model as explained by Behrangi et al. (2011). Note that the simulated hydrographs (**Figure 5(c) and 5(d)**) are transformed using $Q_t = ((Q_s + 1)^{0.3} - 1)/0.3$ (Q_t, transformed runoff; Q_s, simulated runoff) for better visualization of peak flows (Hogue et al. 2000).

A visual comparison indicates that, while the original PERSIANN satellite data can capture the general precipitation patterns (**Figure 5(a)**), the PERSIANN-MBA version (**Figure 5(b)**) leads to a better agreement with reference measurements (gray lines). Note that the original PERSIANN precipitation data overestimate the precipitation intensity, particularly during the spring and summer months (**Figure 5(a)**). On the other hand, the PERSIANN-MBA data show significant improvement in estimating the seasonal variability and magnitude of the precipitation rate (**Figure 5(b)**). Consequently, simulated discharge derived from PERSIANN-MBA data exhibits better agreement with reference measurements (compare **Figure 5(c) and 5(d)**). It should be noted that GPCP and stage IV data sets are not purely independent, as rain gauges are used in both data sets.

Flood forecasting practice also relies on precipitation forecasts from the numerical weather prediction (NWP) models. NWP precipitation forecasts are processed as probabilistic estimates known as quantitative precipitation forecasts (QPF; Amburn 1992; Amburn and Wolf 1994). Obviously, the quality of forecasts will depend on the reliability of the precipitation estimates. However, NWP models may miss precipitation events, particularly small-scale and short-term systems. On the other hand, the initial conditions and variables are typically updated when observations become available. Without regular updating, the NWP model loses its skills in representing the precipitation amount and its space–time variability. Recently, satellite estimates are being assimilated into NWP models to improve the NWP forecasts by providing more observations at regular intervals.

5.09.4 Summary and Concluding Remarks

Water resources decision making in semiarid regions is driven by the need to have reliable water supplies of adequate quality, in the face of stressed surface water and dwindling groundwater supplies. In managing water resources, accurate and uninterrupted information on the quantity of water cycle components is critical for sustainable development. Given the population growth, industrial development, and increasing challenges for sustainable water resources management, innovative approaches to quantify hydrologic variables are highly desirable. In recent years, remote sensing data sets have emerged as major sources of information on hydrologic variables. In the past decades, utilization of remote sensing data in water resources and water cycle studies has increased significantly.

Several climate projections indicate an increase in drought frequency, duration, and severity in the future (WCRP 2010). A major challenge in the development of drought monitoring systems is the lack of information on the indicator variables (e.g., precipitation, soil moisture, and storage). In this chapter, a drought model based on PERSIANN remotely sensed precipitation data is introduced. In a case study, SPIs were estimated for the contiguous United States using PERSIANN precipitation data. The results indicated that the general patterns of wet and dry areas from PERSIANN data were in reasonable agreement with those obtained from gauge data.

One attractive feature of PERSIANN precipitation estimates for drought analysis is the possibility of reconstructing long-term data required for studying droughts. Currently, efforts are underway to provide PERSIANN data continuously for the past 30 years for which IR images are available. We anticipate that the high-resolution, multidecadal PERSIANN data will provide a valuable source of data for quasi-global drought analysis.

Application of PERSIANN and PERSIANN-MBA data sets in streamflow simulation has been discussed in a case study. Previous studies reveal that most unadjusted precipitation data sets, including PERSIANN, tend to overestimate precipitation, particularly over warm months (AghaKouchak et al. 2011; Behrangi et al. 2011). The overestimations (bias) of most satellite precipitation data sets are typically more significant for higher precipitation rates (high quantiles). This limits the application of satellite data in streamflow simulation. The results indicated that the simulated streamflow using the original PERSIANN precipitation data overestimates observed data. Simulated discharge using PERSIANN-MBA, on the other hand, exhibits significant improvement in capturing runoff peaks. Notice that gauge-corrected PERSIANN-MBA is only available at the end of the month as the bias correction is performed in monthly scale. Therefore, this product is not available for real-time analysis.

It is worth pointing out that major achievements have been made in model development; however, without reliable input data (e.g., precipitation), models cannot provide meaningful simulations. Satellites can provide precipitation data over remote locations and ungauged basins, as well as areas with complex terrain where no other means of measurement is available. Given the importance of the quality of input precipitation in hydrological modeling, we predict that in the near future more efforts will be devoted to improve satellite precipitation estimates by using multisensor multispectral approaches.

As mentioned earlier, remotely sensed data sets have several advantages over ground-based measurements such as higher spatial resolution and uninterrupted measurement (e.g., better overall estimation of space–time variability of precipitation). However, these data sets have not yet fully integrated into water resources management and decision-making systems, mainly because of undetermined uncertainties (Hossain and Huffman 2008; Margulis et al. 2006; AghaKouchak et al. 2010b; Dong et al. 2005; Lucieer and Kraak 2004; Bastin et al. 2002; Crosetto et al. 2001). Thus far, extensive research has been devoted to validate and improve satellite precipitation data including PERSIANN data (e.g., Stisen and Sandholt 2010; Shen et al. 2010; Tian et al. 2009; Zeweldi and Gebremichael 2009; Feidas et al. 2009; Liu et al. 2009; Sapiano and Arkin 2009; Durga Rao et al. 2009; Turk et al. 2008; Tuttle et al. 2008; Dinku et al. 2008; Ebert et al. 2007).

We believe that more efforts should be devoted to the validation and verification of satellite data in order to identify the limitations and further develop the data sets for practical applications. While application of satellite precipitation data in water resources and decision making seems to be promising, a great deal of research is necessary to further improve the quality of satellite data for hydrologic applications (e.g., development of more sophisticated bias-adjustment techniques). Furthermore, efforts are required to quantify uncertainty of satellite data, which is a roadblock in the application of satellite data in water resources applications (AghaKouchak et al. 2011; Hossain and Huffman 2008; Margulis et al. 2006; Dong et al. 2005; Hossain and Anagnostou 2005).

As mentioned earlier, global climate models assess potential climatic change impacts on the water cycle. However, climate model outputs have many limitations for operational applications including coarse resolution. It is our view that sustainable water resources management requires tools beyond global climate modeling. Advanced methodologies should be developed along with high-resolution and reliable data sets in scales relevant to operational water resources management (Pielke et al. in press; Sorooshian et al. 2011). It is hoped that future research toward high-resolution quantitative multisensor precipitation with quantified uncertainty leads to a significant advance in water resources management.

5.10.1 Introduction

The force of gravity is directly proportional to mass. Although we may think of gravity as being a constant at 9.8 m s^{-2}, mass is not uniformly distributed at the Earth's surface and therefore gravity is nonuniform as well. Earth's gravity field can be visualized as a bumpy ellipsoid, having both static and time-variable components, the static component being orders of magnitude stronger. Jeffreys (1952) was among the first to report the existence of the time-variable component, noting that mass movements such as ocean tides changed the gravity field.

From the perspective of an orbiting satellite, the Rocky Mountains exert more gravitational force than the Great Plains and eastern Asia exerts more gravitational force during monsoon season, when the ground is wet and therefore more dense, than during the dry season. The orbit of such a satellite is perturbed in a way that can be predicted based on the gravitational potential and thus, the surface mass distribution, or vice versa. Realizing this, scientists began to use the orbits of artificial satellites to identify spatial irregularities in the Earth's gravity field in the late 1950s. Satellite tracking via optical and Doppler techniques allowed them to compute departures from predicted orbits, and from these values, the static gravity field was mapped. In the 1960s, satellite laser ranging enabled more accurate determination of satellite orbits and thus more detailed assessments of the gravity field. Yoder et al. (1983) reported that the orbit of the Lageos satellite was sensitive to temporal variations in the gravity field, which was a first glimpse at the future of time-variable gravity field mapping.

For the purpose of mapping Earth's time-variable gravity field with enough accuracy to be useful for such applications as ocean, ice sheet, and terrestrial hydrology monitoring, geodesists realized that tracking satellite orbits from the surface was too imprecise. Instead, they concluded that a dedicated twin satellite gravimetry mission, with each satellite tracking the orbit of the other, was the best strategy (Dickey et al. 1997). Plans for the Gravity Recovery and Climate Experiment (GRACE) satellite mission soon followed.

GRACE, launched on 17 March 2002, was sponsored jointly by NASA and its German counterpart. In addition to improving the resolution and accuracy of global gravity maps by more than two orders of magnitude, GRACE proved to be immensely valuable for oceanography, cryospheric science, and hydrology. Perhaps the most renowned climate-related application of GRACE is the estimation of mass losses from the Greenland and Antarctic ice sheets and the associated sea level rise (e.g., Velicogna and Wahr 2006a,b; Luthcke et al. 2006). Similarly, GRACE has measured the ablation of major glacier systems in Alaska (Tamisiea et al. 2005; Luthcke et al. 2008), South America (Chen et al. 2007), central Asia (Matsuo and Heki 2010), and the Canadian Arctic Archipelago (Gardner et al. 2011). GRACE has also contributed to numerous studies in many areas of hydrology, including river discharge estimation (Syed et al. 2009), regional evapotranspiration (Rodell et al. 2004; Swenson and Wahr 2006a), hydroclimatic teleconnections (Andersen et al. 2005; Crowley et al. 2006), groundwater variability (Yeh et al. 2006; Rodell et al. 2007), and drought monitoring (Houborg et al. 2012).

Thus, satellite gravimetry as demonstrated by GRACE lends itself to the study of climate vulnerability, particularly water resources change. This chapter provides details of the GRACE mission and the data it provides (see Section 5.10.2); describes examples of GRACE-enabled investigations of hydroclimate and hydroresources variability including groundwater (see Section 5.10.3), surface waters, and glaciers (see Section 5.10.4), integration of GRACE and other data within numerical models (see Section 5.10.5), and drought monitoring; and reports on future prospects of satellite gravimetry.

5.10.2 GRACE Data: Unique and Challenging

The GRACE mission consists of two satellites in a near-polar orbit, about 200 km apart, at a starting altitude of about 500 km. The precise distance between the satellites is constantly measured using a K-band microwave ranging system. The range measurements along with positioning data are used to construct a new map of Earth's gravity field each month, represented mathematically by a set of spherical harmonic coefficients describing the shape of the global gravity field (Tapley et al. 2004). From these monthly 'gravity field solutions,' time series of regional mass anomalies can be derived using specially designed averaging functions (Wahr et al. 1998).

Unlike conventional remote sensing techniques that rely on measurements of various wavelengths of light emitted or reflected from the Earth's surface, vegetation, or atmosphere, satellite gravimetry is not blind to subsurface conditions. GRACE senses variations in the total mass from the top of the atmosphere to the center of the Earth. Oceanic and atmospheric circulations and redistribution of terrestrial water via the hydrological cycle are the main sources of gravitational variability on time scales of months to years. Numerical model analyses are used to estimate and remove the oceanic and atmospheric effects, leaving variations in terrestrial water storage (TWS; the sum of groundwater, soil moisture, surface water, snow, ice, and vegetation biomass) as the only major signal over land. Glacial isostatic adjustment also must be taken into account in certain regions such as Hudson's Bay in Canada and the Scandinavian peninsula, and the Sumatra–Andaman earthquake of 2004 and the Japanese Tohoku earthquake of 2011 produced huge abrupt gravitational anomalies in those regions. However, the time scales of most solid earth processes are too long to be relevant.

What has made GRACE uniquely valuable to hydrology is its ability to measure variations in total water availability on and in the land surface, without limitations of depth, visibility, or location on the Earth. However, the satellite gravimetry method has its own set of challenges. First, instead of having a remote sensing footprint or pixel resolution, there is a tradeoff between resolution and accuracy. The gravity field solutions contain larger errors at higher degrees and orders (smaller length scales). At resolutions finer than about 150 000 km^2, the uncertainty in the estimates overwhelms the retrieved mass variations (Rodell and Famiglietti 1999; Rowlands et al. 2005; Swenson et al. 2006). Second, measuring changes in all components of TWS at once is a double-edged sword. GRACE provides no information on the vertical structure of a TWS change, whether in the saturated zone, shallow subsurface, surface waters, or ice and snow cover. Third, most hydrologists are accustomed to working with instantaneous or daily observations of an absolute quantity, such as rainfall rate or snowpack depth, whereas GRACE provides monthly mean estimates of TWS anomalies (deviations from the long-term average). A related issue is that a monthly observational cycle (for the standard products) ensures that GRACE data will never be available close to real time. The standard products are typically available a couple of months after the fact. Development of an expedited product is being studied by the GRACE science team, but that still would not meet the needs of most operational water resources and weather-related applications.

5.10.3 Groundwater Depletion Assessment

Clearly, real-time data are not required for all applied or scientific hydrology applications. Quality and duration of observations are more important for assessing groundwater variability and depletion. In order to employ GRACE data for this purpose, groundwater storage must be isolated from the other components of TWS. A simple approach is to use auxiliary data to estimate variations in soil moisture and snow water equivalent and to subtract these from TWS variations, leaving variations in groundwater storage as a residual. The assumption here is that temporal variability of vegetation biomass and surface water storage is negligible relative to that of groundwater, soil moisture, and, depending on the region, snow mass. Rodell et al. (2005) demonstrated that seasonal and interannual changes in biomass are at or below the limits of detection by GRACE. Outside humid tropical regions such as the Amazon (Han et al. 2009) and Bangladesh (Shamsudduha et al. 2012), surface water storage mass variations are also typically insignificant relative to soil moisture, groundwater, and snow mass variations (Rodell and Famiglietti 2001; Rodell et al. 2009). However, networks of soil moisture (and snow) measurement sites that are dense enough to construct reliable time series of regional mean water storage variability are rare (e.g., Yeh et al. 2006). Rodell et al. (2007) demonstrated that soil moisture and snow time series from numerical land surface models (LSMs) were a reasonable alternative, deriving a time series of groundwater storage in the Mississippi River basin that compared favorably with a time series based on groundwater well observations.

The High Plains aquifer of the central United States, whose groundwater depletion is well documented (e.g., Luckey et al. 1981), provides a useful case study for evaluating the ability of GRACE to monitor interannual variations in groundwater storage. As in many other agricultural regions where rainfall is frequently insufficient to support crop production demands, groundwater withdrawals for irrigation exceed recharge over the long term. This has caused the water table to decline at an average rate of about 7.2 cm year^{-1} since 1950, which is equivalent to a reduction in water storage of 337 km^3 between 1950 and 2009 (McGuire 2011). The rates of water table decline are greater in the central and southern parts of the aquifer, reaching more than 80 cm year^{-1} in some areas of the Texas panhandle.

Strassberg et al. (2007) combined GRACE TWS observations with soil moisture output from the Global Land Data Assimilation System (GLDAS; Rodell et al., 2004) to compute groundwater variations in the High Plains aquifer during 2003–2005. The correlation coefficient between observed and GRACE-derived monthly groundwater storage was determined to be 0.58, although the time period was too short to assess the efficacy of the GRACE technique for monitoring interannual variability. A subsequent analysis by Strassberg et al. (2009) improved on those results in a study covering the period 2003–2007 with a more optimally derived GRACE TWS time series and both observational and model-based soil moisture data, achieving correlation coefficients of 0.73 and 0.72, respectively, between observed and GRACE-based monthly groundwater storage time series.

Another area of the United States that may be overly dependent on groundwater is California's Central Valley. Thanks to its favorable climate and good soil, the Central Valley supports a wide variety of crops and is considered one of the most productive agricultural regions of the world. However, sustaining this productivity requires a rate of rainfall that is not consistently available and may be well short during dry years. The proximal solution is fed by irrigation by water from the aquifer beneath the Sacramento and San Joaquin river basins, which are mainly recharged by melting snow from the Sierra

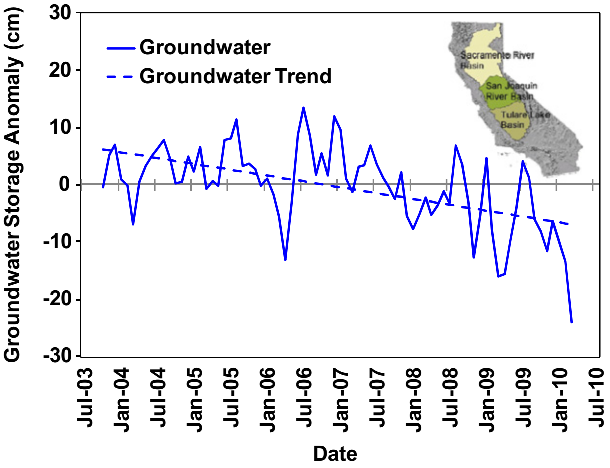

Figure 1 Time series of GRACE-estimated groundwater anomalies (with linear trend) as an equivalent height of water in centimeters, averaged over California's Sacramento, San Joaquin, and Tulare lake basins (inset). Source: Modified from Famiglietti, J. S., and Coauthors, 2011: Satellites measure recent rates of groundwater depletion in California's Central Valley. *Geophys. Res. Lett.*, **38**, http://dx.doi.org/10.1029/2010GL046442.

Nevada Mountains (Faunt 2009). Famiglietti et al. (2011) used GRACE data spanning October 2003–March 2010 to estimate that the Sacramento and San Joaquin river basins (154 000 km^2) lost water at an average rate of 4.8 km^3 year^{-1} (Figure 1), about two-thirds of which was groundwater pumped from the Central Valley. They concluded that groundwater depletion at this rate was unsustainable and would have serious consequences if unabated. Fortunately for California, exceptionally wet weather during the winter of 2010–2011 helped the Central Valley aquifer to recuperate to some extent, delaying those consequences for the time being.

The starkest example of groundwater mining over a large area is in northern India. Such a massive quantity of water is being removed from this region that it stands out like a bull's eye on a global map of trends in the gravity field derived from GRACE data (Figure 2). Although officials in India have long been aware that groundwater withdrawals exceed recharge on annual average across the Indian states of Rajasthan, Punjab, and Haryana (including Delhi), an integrative assessment of the rate of depletion had not been performed before the onset of GRACE. Rodell et al. (2009) used GRACE TWS data and simulated soil moisture from the GLDAS to determine that groundwater was depleted at a mean rate of 17.7 ± 4.5 km^3 year^{-1} between August 2002 and October 2008 over the 438 000 km^2 region (Figure 3). This equates to 4.0 ± 1.0 cm year^{-1} equivalent layer of water (about 33 cm of water table decline per year) and a total of 109 km^3 of groundwater during the study period, which is triple the capacity of Lake Mead, America's largest man-made reservoir. Annual rainfall was close to normal throughout the period, which rules out the possibility of drought-related TWS diminishment, and it was determined that surface water and other TWS components did not contribute significantly to the observed trend. Analyzing a 2 700 000-km^2 surrounding area of northern India in a similar GRACE-based study, Tiwari et al. (2009) estimated a groundwater depletion rate of 54 ± 9 km^3 year^{-1}. Currently, farmers are given free electricity for groundwater pumping, so there is no incentive for conservation, yet there is great resistance to changing this policy. The desire for water-intensive crops, rice in particular, exacerbates the problem. A sustainable solution to avert hydrological and agricultural catastrophe for the 600 million residents of the broader region will require creativity, political will, and, above all, acceptance of the need for change.

A similar situation exists just to the east in the Bengal basin of Bangladesh. Groundwater abstraction for irrigating dry season rice crops along with reduced recharge because of urbanization has depleted the aquifers over the past 40 years. Groundwater abstraction is believed to mobilize arsenic, putting further pressure on this vital yet vulnerable resource (Ahmed et al. 2004). It is unclear how future climate change (e.g., if the South Asian monsoon shifts in location or intensity) would affect groundwater storage dynamics. Shamsudduha et al. (2012) compared ground-based observations with GRACE TWS data and confirmed that GRACE captures both the seasonality and the trend of groundwater storage in the Bengal Basin, making it valuable for water resources assessment in the region. They found that groundwater storage accounted for the greatest proportion of total variability in TWS in the basin, at 44%, with soil moisture and surface water storage accounting for 33% and 22% of variability, respectively. The rate of groundwater depletion based on GRACE observations during 2003–2007 was estimated to be 0.5 ± 0.3 km^3 year^{-1}.

5.10.4 Lakes and Glaciers

Inland surface waters are another resource that is vulnerable to overexploitation and drought, effects that can be detected by GRACE if the mass changes are large enough. Seasonal water storage changes in the Amazon River system are the largest in the world, and interannual variability, mainly because of El Niño Southern Oscillation cycles, is similarly immense. Because Amazon surface waters are often dispersed across the landscape rather than concentrated in distinct river channels, ground-based quantification of total storage and flow volumes is imprecise. Thus, several studies have applied GRACE observations to refine understanding of water cycle variability and surface water dynamics in the Amazon River basin (e.g., Han et al. 2009; Alsdorf et al. 2010). Awange et al. (2008), Swenson and Wahr (2009), and Becker et al. (2010) used GRACE to study water level changes in east African lakes, which are affected by both climatic variability and water resources management, both poorly documented. Swenson and Wahr (2009) used GRACE data together with satellite-altimetry-based lake levels to infer the water balance of Lake Victoria and the surrounding region. Results were compared with reservoir management data as available and results from previous studies. They concluded that at least half of the observed lake level declines during 2002–2006 were caused by releases from Lake Victoria's dams in excess of amounts approved via international treaty (lake discharge being used for hydroelectric power generation). Other surface water bodies whose water storage variability has been elucidated by GRACE include the

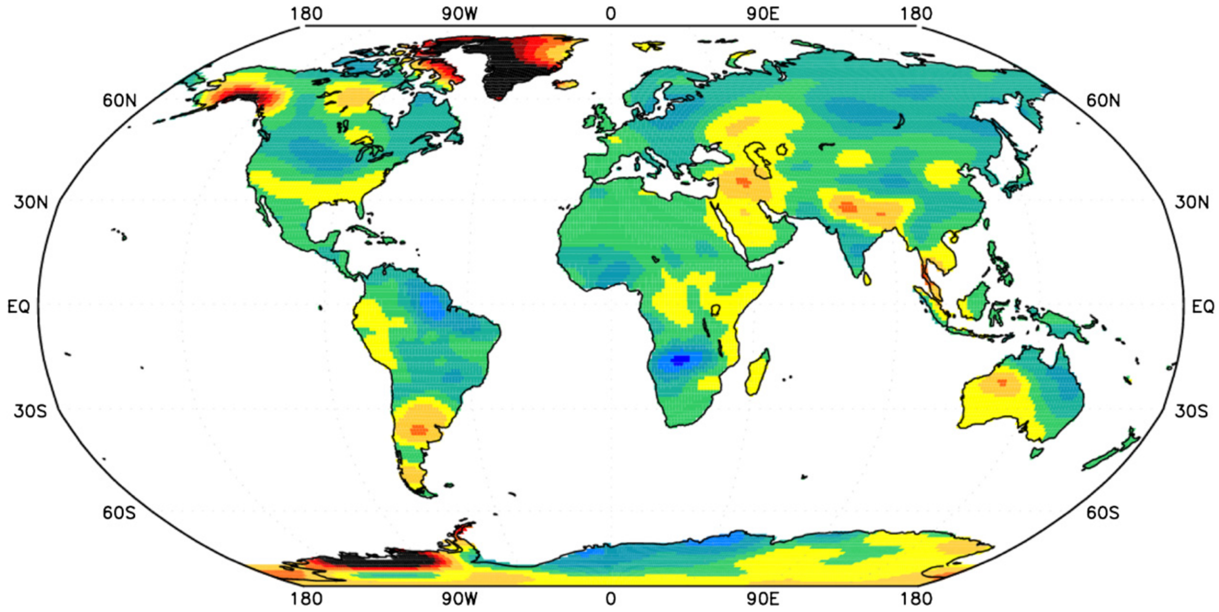

Figure 2 Mean rates of change ('trends') of terrestrial water storage (centimeters per year) based on GRACE data from August 2002–August 2011. The effects of postglacial rebound have been removed from the GRACE data using the model of Paulson et al. (2007), but the gravitational effects of major earthquakes in Sumatra (2004) and Japan (2009) distort the estimated trends near those locations.

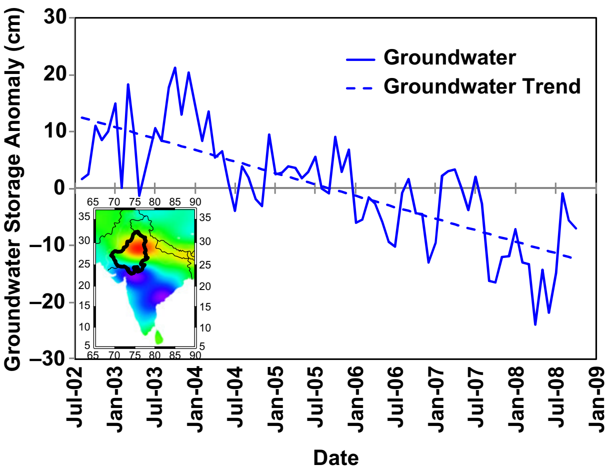

Figure 3 Time series of GRACE-estimated groundwater anomalies (with linear trend) as an equivalent height of water in centimeters, averaged over the Indian states of Rajasthan, Punjab, and Haryana. The inset outlines the region in black on a map of groundwater trends, with depletion in warmer shades. Source: Modified from Rodell, M., I. Velicogna, and J. S. Famiglietti, 2009: Satellite-based estimates of groundwater depletion in India. *Nature*, **460**, 999–1002, http://dx.doi.org/10.1038/nature08238.

Caspian Sea (Swenson and Wahr 2007), Lakes Baikal and Balkhash (Hwang et al. 2011), and the Three Gorges Reservoir (Wang et al. 2011).

Glaciers store freshwater and release it gradually in warm seasons, making them an important resource that happens to be very susceptible to climate variability and longer-term change. Over the past decade or more, several of the world's major glacier systems have been melting fast enough such that the associated mass change signals are observable by GRACE. While thinning of Greenland's ice sheet has attracted most of the attention in the Arctic region (e.g., Velicogna and Wahr 2006a,b; Luthcke et al. 2006), Gardner et al. (2011) recently made use of GRACE to determine that the melt rate from ice caps and glaciers of the Canadian Arctic Archipelago is equivalent to about 61 km^3 year^{-1} of water, or 0.17 mm year^{-1} sea level rise. For comparison, Greenland loses about 219 km^3 year^{-1}, or 0.61 mm year^{-1} sea level rise (Chen et al. 2011). Tamisiea et al. (2005) and Luthcke et al. (2008) showed that glaciers along the southern coast of Alaska are melting at a rate of about 84 km^3 year^{-1} (0.23 mm year^{-1} sea level rise). Chen et al. (2007) calculated that Patagonian glaciers in southern South America are losing 28 km^3 year^{-1} (0.08 mm year^{-1} sea level rise). Matsuo and Heki determined using GRACE that ice water storage losses from the Tibetan Plateau were at least 47 km^3 year^{-1} (0.13 mm year^{-1} sea level rise) during 2003–2009, which is double the estimated rate of the preceding 40 years, and that the rate could be as high as 61 km^3 year^{-1} depending on glacial isostatic adjustment beneath the plateau.

5.10.5 GRACE Data Assimilation

While the previous sections clearly demonstrate that GRACE observations have been valuable for a range of hydrological studies, decision support and most other applied disciplines require data that have higher resolution and are available closer to real time. With this as the motivation, Zaitchik et al. (2008) introduced a more sophisticated approach for spatially, temporally, and vertically disaggregating GRACE-derived terrestrial water storage while simultaneously allowing the information to be extended to near real time. The approach

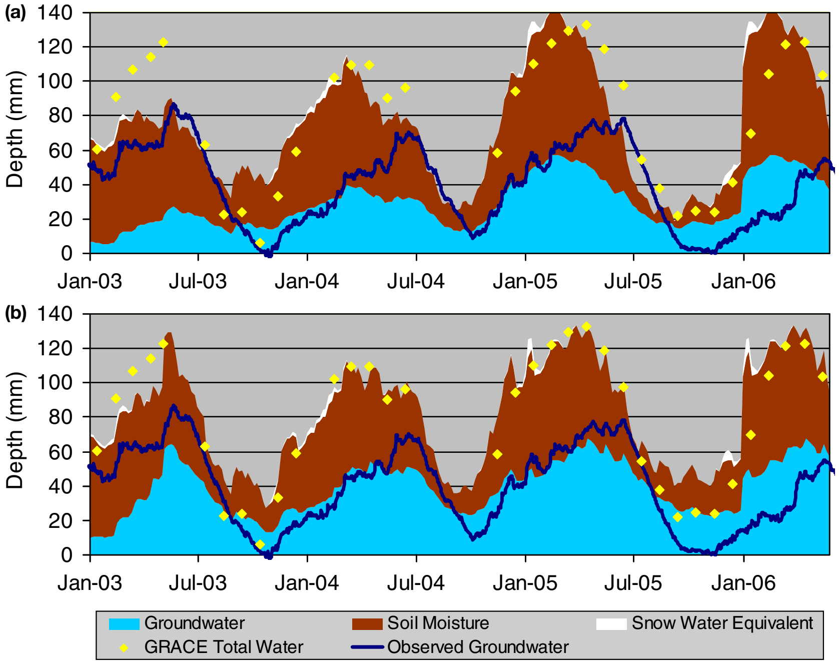

Figure 4 Groundwater, soil moisture, and snow water equivalent averaged over the Mississippi River Basin from (a) open loop Catchment land surface model and (b) GRACE data assimilation. Also shown are daily observation-based groundwater and monthly GRACE-derived TWS anomalies. GRACE and modeled TWS were adjusted to a common mean, as were observed and modeled groundwater. The correlation coefficient between simulated and observed groundwater improved from 0.59 (open loop) to 0.69 (GRACE-DAS). Unlike GRACE alone, the assimilated product is 3-hourly and vertically distributed. Source: Modified from Zaitchik, B. F., M. Rodell, and R. H. Reichle, 2008: Assimilation of GRACE terrestrial water storage data into a land surface model: results for the Mississippi River Basin. *J. Hydrometeor.*, **9**(3), 535–548, http://dx.doi.org/10.1175/2007JHM951.1.

employs an ensemble Kalman smoother to assimilate GRACE data into a numerical LSM. This has several advantages. First, physical equations of hydrologic and energetic processes, integrated within the model, provide a basis for synthesizing GRACE and other relevant observations (e.g., precipitation, solar radiation, land cover) in a physically consistent manner. Second, the model fills spatial and temporal data gaps, while observations anchor the results in reality. Third, in addition to separating groundwater, soil moisture, and snow, the assimilated output has much higher spatial and temporal resolutions than the original GRACE data. Zaitchik et al. (2008) selected the Catchment LSM for this purpose, mostly because it simulates groundwater storage variations, a prerequisite that most models do not satisfy. They chose to use an ensemble Kalman smoother rather than the more common Kalman filter because the filter assimilates observations as they become available and updates only the most recent model states, whereas smoothers use information from a series of observations to update model states over a window of time (Dunne and Entekhabi 2005; Evensen and van Leeuwen, 2000). Smoothers are therefore well suited for GRACE observations, which are noninstantaneous. Before assimilation, GRACE TWS anomalies are converted to absolute TWS values by adding the corresponding regional time-mean water storage from the open loop (no data assimilation) portion of the Catchment model simulation. Zaitchik et al. (2008) validated the technique in the Mississippi River basin using groundwater data from a network of wells and showed significant improvement in both the timing and amplitude of modeled groundwater variations (Figure 4). The correlation coefficient between the simulated and observed groundwater storage time series improved from 0.59 to 0.69 because of GRACE data assimilation. Furthermore, it was shown that GRACE data assimilation affects modeled evapotranspiration and runoff fluxes. In addition to drought monitoring (described in the next section), GRACE data assimilation has now been applied for snowpack quantification in the Mackenzie River basin (Forman et al. 2012), water cycle characterization in western Europe (Li et al. 2012), and water resources assessment in the Middle East and North African region (Bolten et al. 2010).

5.10.6 Drought Monitoring

Drought has devastating impacts on society and costs the US economy 6–8 billion dollars per year on an average (WGA 2004). Drought affects the availability of water for irrigation, industry, and municipal usage; it can ravage crops, forests, and other vegetation, and, where rivers support hydropower and power plant cooling, it affects electricity generation. Most current drought products rely heavily on precipitation indices and are limited by the scarcity of reliable objective information on subsurface water stores. Groundwater levels, which integrate meteorological conditions over time scales of weeks to years, would be particularly well suited to drought monitoring, if only such data were available with some semblance of spatial

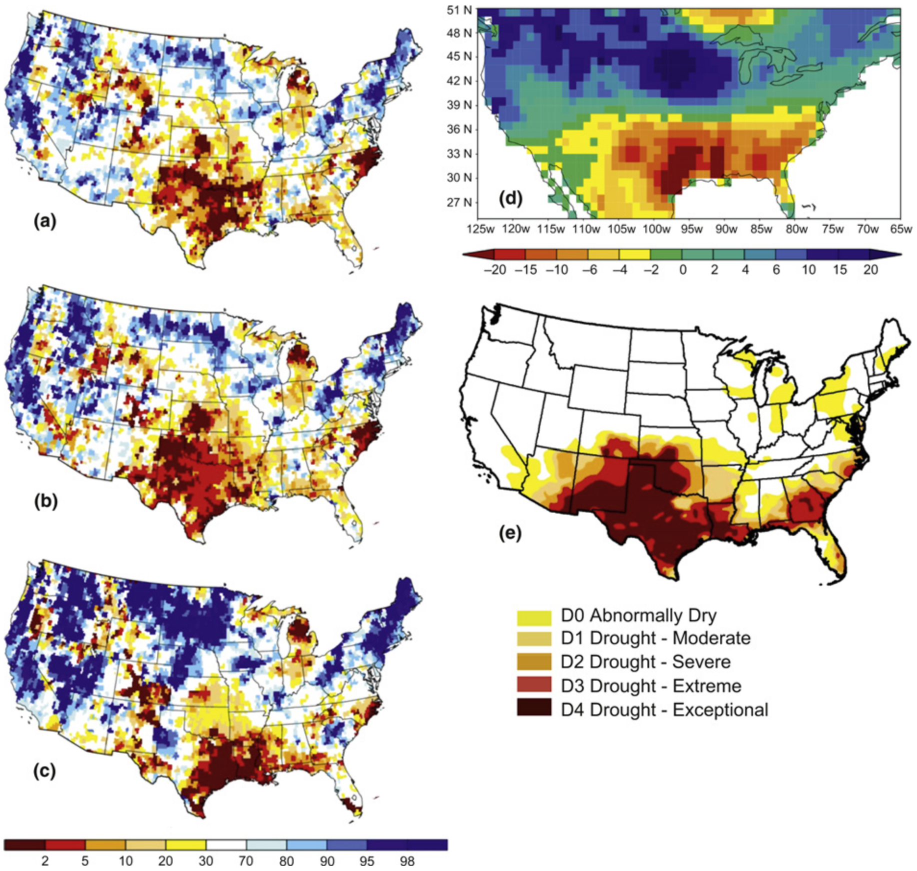

Figure 5 GRACE-based drought indicators (wetness percentiles) of surface soil moisture (a), root zone soil moisture (b), and groundwater (c) for 27 July 2011, compared with the GRACE terrestrial water storage anomalies (centimeter equivalent height of water) for July 2011 (d) and the US Drought Monitor product for 26 July 2011 (e). Source: Li, B., M. Rodell, B. F. Zaitchik, R. H. Reichle, R. D. Koster, and T. M. van Dam, 2012: Assimilation of GRACE terrestrial water storage into a land surface model: evaluation and potential value for drought monitoring in Western and Central Europe. *J. Hydrol.*, **446–447**, 103–115, http://dx.doi.org/10.1016/j.jhydrol.2012.04.035.

and temporal continuity and a reasonably long background climatology (Rodell 2010).

Droughts cause declines in all types of terrestrial water storage, and as a result, they stand out in the GRACE data. For example, drought in the southeastern United States (2007–2008) imparted a negative trend in that area in Figure 2. GRACE has been applied directly to investigate a decade long drought in southeastern Australia (Awange et al. 2009; Leblanc et al. 2009). Yirdaw et al. (2008) characterized TWS changes associated with a recent drought in the Canadian prairie. Chen et al. (2009) used GRACE to study a major drought event in the Amazon that occurred in 2005, and Chen et al. (2010) examined a recent drought in the La Plata Basin.

Houborg et al. (2012) applied the GRACE data assimilation approach to enhance the value of GRACE for drought monitoring, developing surface and root zone soil moisture, and groundwater drought indicators for the continental United States. Because a long-term record is needed as background to quantify drought severity, whereas GRACE data are only available from mid-2002, it was necessary to rely on the Catchment LSM alone for most of the record. Therefore, Houborg et al. (2012) executed an open loop model simulation for the period 1948 to near present using for input a meteorological forcing dataset developed at the Princeton University (Sheffield et al. 2006). Monthly GRACE TWS anomaly fields (Swenson and Wahr 2006b) were converted to absolute TWS fields by adding the time-mean total water storage field from the open loop Catchment model simulation. This assured that the assimilated TWS output would be nearly identical to that of the open loop, which is to say that there was no discontinuity between the open loop and assimilation portions of the run. However, the GRACE data, and therefore the assimilation results, could still have a larger or smaller range of variability than the open loop land surface model (LSM) results at any given location. This is significant because drought monitoring concerns the extremes. Therefore, to correct for differences in the range of variability between the assimilation and the open loop model output, Houborg et al. (2012) computed and mapped between the cumulative distribution functions of wetness at each model pixel for the open loop and assimilation results during the overlapping period (2002 onward). Drought indicator fields for surface (top several centimeters) soil moisture, root zone soil moisture, and groundwater were then generated based on the probability of occurrence in the output record since 1948. To mimic other drought indicators that contribute to the US Drought Monitor product, dry conditions were characterized from D0 (abnormally dry) to D4 (exceptional), corresponding to decreasing cumulative probability percentiles of 20–30%, 10–20%, 5–10%, 2–5%, and 0–2%. Following this process, new GRACE-data-assimilation-based drought indicators (Figure 5) are now being produced on a weekly basis by NASA and disseminated from the University of Nebraska's National Drought Mitigation Center web portal. They are also being delivered to the principals of the US Drought Monitor, who are currently assessing them as new inputs. The US Drought Monitor is the premier decision support tool for drought in the United States; however, it lacked spatially continuous groundwater and soil moisture inputs before the development of the new GRACE-based drought indicators. Currently, there are very few drought assessment products available that have global coverage, and those that do exist lack the sort of information on subsurface water stores that GRACE provides. It is likely that the GRACE-based drought indicators just described will be extended to the global scale in the near future to help alleviate this knowledge gap.

5.10.7 Future Prospects

Satellite gravimetry is the only remote sensing technology currently available for measuring water stored below the first few centimeters of the soil column or the total liquid and frozen water storage. In addition to GRACE, two other advanced gravity monitoring satellites have been launched: Germany's Challenging Minisatellite Payload (CHAMP) in 2000 and the European Space Agency's Gravity Field and Steady-State Ocean Circulation Explorer (GOCE) in 2009. CHAMP and GOCE each significantly advanced the capability to map the static gravity field at their times of launch, GOCE with significantly higher spatial resolution than GRACE, but neither was suitable for monitoring the time-variable gravity field and inferring changes in TWS (Han and Ditmar 2008).

GRACE has endured well beyond its designed 5-year mission lifetime, and there is no set end date. Depending on battery and instrument health and fuel consumption for orbital adjustments, the mission might continue into the middle of the 2010s. NASA, Germany's space agency, the European Space Agency, and various other organizations have begun discussions of a next-generation satellite gravimetry mission, which would improve on GRACE's horizontal resolution by up to an order of magnitude. This could be achieved by replacing the microwave ranging system with a laser interferometer, flying at a lower altitude in atmospheric-drag-free spacecraft (NRC 2007), and possibly maintaining multiple satellite pairs in orbit simultaneously (Wiese and Nerem 2011). While the improved resolution would be valuable, the need for further downscaling via data assimilation would remain. In the meantime, NASA has begun the development of a follow-on to GRACE with a nearly identical mission design, which would provide continuity in the data record while affording some improvement in resolution because of basic technological advancements of the past 10 years (Watkins et al. 2011). This mission could launch as soon as 2016 and enable gravimetry-based water availability monitoring into the next decade.

Water is essential to life and vulnerable, for example, to overexploitation, pollution, and redistribution associated with any changes in precipitation and temperature. The information provided by GRACE and future satellite gravimetry missions has great potential to improve monitoring and understanding of freshwater availability, thereby helping to reduce environmental and social consequences. The hydrology and other climate communities have been somewhat slow to embrace GRACE as a tool of the trade because of the unique and challenging aspects of the observations. However, success stories such as those described here are increasing awareness and building momentum for GRACE-enabled research and applications. Extending the data record by maintaining GRACE and launching the GRACE follow-on mission will also reduce uncertainty in and improve the understanding of climatic and anthropogenic impacts on the water cycle that have begun to be revealed. Hopefully, as these impacts become less equivocal, stakeholders and policymakers will make better decisions and reduce threats to our precious freshwater resources.

Glossary

Hydrograph A time series showing the changes of river flow.

Pan-Arctic The northern land mass defined by all drainage basins flowing to the Arctic Ocean and northern seas.

River Discharge The volume of water passing through a specific cross section of river during a specific time (examples include $m^3\ s^{-1}$ and $km^3\ year^{-1}$).

Runoff The area normalized river discharge over a defined drainage area. Units are expressed as a depth, typically in mm.

Stage height Measured water level of a river used to determine the volume of flow.

5.11.1 Introduction

The Arctic is undergoing marked changes in response to climate. Numerous studies indicate that the global climate signal in the Arctic is pronounced and has already exceeded natural climate variability (ACIA 2005). All components of the arctic ecosystem are intimately linked to all others and water plays a central and unique role in this system. There is mounting evidence that the region is experiencing an unprecedented degree of environmental change in various components of the water cycle. These include loss of permafrost (Yang et al. 2002); change in river flow volume (Lammers et al. 2001; Peterson et al. 2002; Shiklomanov and Lammers 2009) and timing (Shiklomanov et al. 2007; Tan et al. 2011); lengthened ice-free periods in lakes and rivers (Magnuson et al. 2000; Vuglinsky 2002); disappearance of lakes (Smith et al. 2005); reductions in snow cover (Armstrong and Brodzik 2001); and melting of glaciers (Steffen et al. 2004). Streamflow changes are strongly related to climate variability, disturbance in land cover, degradation of the cryosphere, and direct human impact. River flow is an integrated characteristic reflecting numerous environmental processes and their changes aggregated over different size areas. River runoff also plays a significant role in the freshwater budget of the Arctic Ocean (Serreze et al. 2006). Ocean salinity and sea ice formation are critically affected by river input. Changes in the freshwater flux to the Arctic Ocean can exert significant control over global ocean circulation by affecting North Atlantic deep water formation (Manabe and Stouffer 1994; Rahmstorf 2002). Arctic drainage basin river flow is thus likely to serve an important role in regulating the heat balance of the planet (Peterson et al. 2006). The freshwater cycle of the Arctic therefore takes on a central role in our understanding of the influence of global change on terrestrial ecosystems and on the connection of the northern land mass to the Arctic Ocean (Lammers et al. 2001).

5.11.1.1 Definition of Domain

Our understanding of the Arctic Ocean's freshwater budget variability requires analysis of hydrological processes across the entire river runoff formation zone covering both the Arctic Ocean watershed and the adjacent territories from which the runoff contributes to the ocean freshwater budget. The entire Pan-Arctic hydrological domain covers a region of approximately 24 million km^2(including Greenland) and represents a significant part of the global land surface in the north. The region is characterized and defined hydrologically by the north flowing rivers entering the Arctic Ocean, Hudson Bay, James Bay, the Canadian Arctic Archipelago, the far north Atlantic Ocean, and Bering Strait including much of Alaska (Shiklomanov et al. 2000; Lammers et al. 2001; Forman et al. 2000) (**Figure 1**). Although the Hudson Bay, James Bay, and Bering Strait are located outside of the Arctic Ocean drainage basin, the rivers draining into these water bodies supply a large amount of freshwater discharge to the Arctic Ocean via the north-flowing oceanic currents (AMAP 1998). Thus, it is important to take into account the river discharge from these drainage basins when assessing the dynamics of the river flux into the Arctic Ocean. The headwaters of the large Arctic rivers such as Nelson, Ob, and Yenisey drainage basins extend halfway to the equator to a latitude of 45°N. Thus, a significant

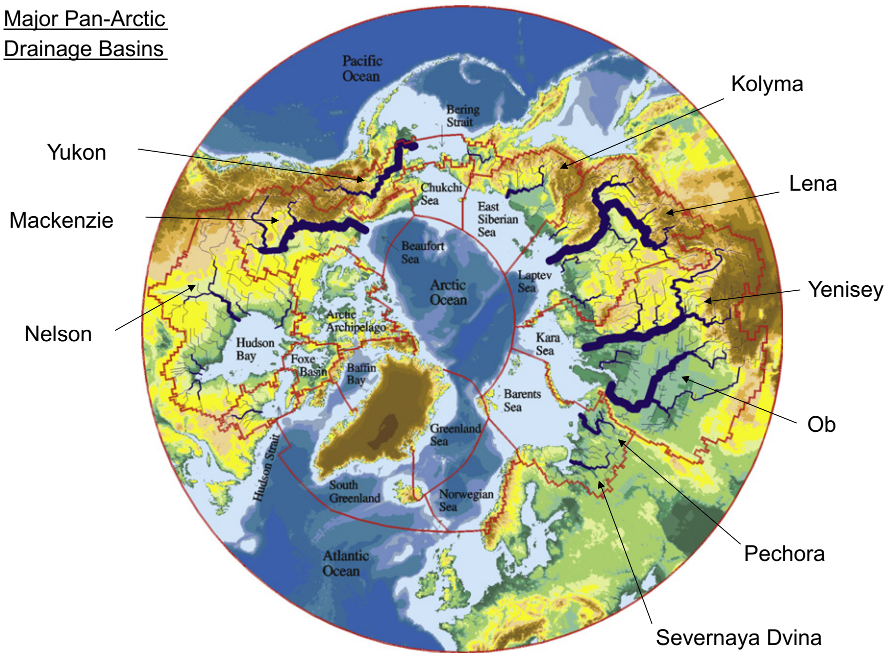

Figure 1 Major northern rivers (dark blue lines) and seas (red outlines) of North America and Eurasia. Background coloring shows elevation and bathymetry relative to sea level. Forman, S. L., W. Maslowski, J. T. Andrews, D. R. Lubinski, M. Steele, J. Zhang, R. Lammers, and B. Peterson, 2000: Researchers explore arctic freshwater's role in ocean circulation. *EOS Trans. Am. Geophys. Union*, **81**, 169–174.

part of the Pan-Arctic hydrological domain is located in temperate climate zones and is covered not only by tundra, but also by boreal–taiga forest and grassland.

5.11.2 Current Status of Discharge Monitoring

This section explores the status of river monitoring at high latitudes, what data is being collected, how good this data is, what parts of the domain are regularly monitored, and how have changes in the gauging network altered over time. Each of these components is critical to understanding the true nature of the observed changes and how these have impacted the humans in the northern latitudes.

Access to comprehensive and reliable data on Arctic hydrology is of crucial importance for studies focusing on the role of the Arctic in the climate system. The rivers draining to the Arctic Ocean redistribute moisture from temperate regions to the high latitudes, and also connect very large and heterogeneous areas to the Arctic Ocean and its shelf seas (Arctic-HYDRA 2010).

Few of the major measured components of the hydrological cycle are considered to have sufficient accuracy to support a full closure of the water budget. Groundwater fluxes tend to be poorly known and evapotranspiration is rarely measured in sufficient sampling density over large regions. Measurement of rainfall is carried out more regularly, but in cold regions this only accounts for a fraction of total precipitation. Solid precipitation measurement is known to have large systematic and random errors, often with large uncertainties arising from the use of imperfect gauging techniques (Goodison et al. 1998). The errors for solid precipitation can reach 70% and higher in northern regions under windy conditions (Golubev 1969; Goodison 1978; Groisman and Easterling 1994; Goodison et al. 1998). At the same time, river discharge is believed to be one of the most accurately measured components of the hydrological cycle (Dingman 2001; Vörösmarty et al. 2001), integrating drainage basin behavior over a range of scales. River discharge is thus one of the most important monitoring tools for understanding the water cycle and the observed data has generally higher quality than observations of other major water balance components. Shiklomanov et al. (2006) evaluated the accuracy of river discharge observations for large Russian rivers flowing into the Arctic Ocean. They found that mean relative errors of daily discharge varied from less than 3% during the summer months (Pechora at UstTsilma, Ob at Salekhard) to more than 40% during ice-affected periods (Kolyma at Srednekolymsk). However the errors of monthly and annual discharge estimates are greatly reduced, as a result of aggregation and usually do not exceed 10% (Shiklomanov et al. 2006).

While there are large networks of observations available, there are several problems preventing a true Pan-Arctic picture from emerging. These include the following:

1. The density of monitoring stations is highly variable with a very sparse river gauge network in low populated areas.
2. During the 1990s, there was a significant net decline in monitoring sites in the Eurasian and North American Pan-Arctic (Figure 2 and Shiklomanov et al. 2002);
3. Delay in official data reporting from one to several years and restricted access to the Eurasian Pan-Arctic data;
4. Significant uncertainty of discharge estimates where available in near real time.

In the United States, the U.S. Geological Survey (USGS) is the primary agency that monitors streamflow; although many stream gauges are funded through partnerships with other federal, state, and local agencies. The USGS currently operates more than 120 stream gauges in Alaska and this number has

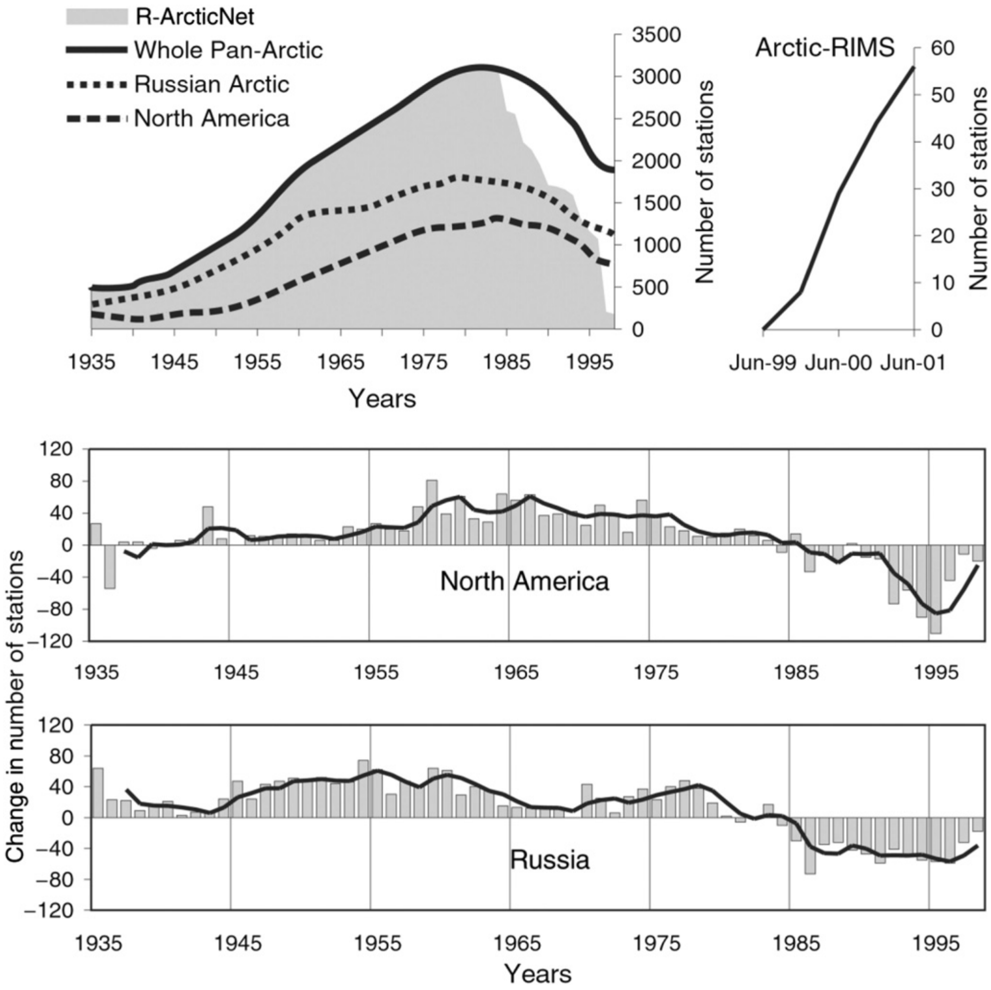

Figure 2 Dynamics of the river gauges in the Pan-Arctic drainage basin and data available in total R-ArcticNet, the operational Arctic-RIMS project, and changes in the number of river discharge gauges in North America and Russia are shown. In 1999, the discharge monitoring network had the same number of gauges as in 1960. Source: Shiklomanov, A. I., R. B. Lammers, C. J. Vorosmarty, 2002: Widespread decline in hydrological monitoring threatens Pan-Arctic research. *EOS Trans. Am. Geophys. Union*, **83,** 13–17.

been relatively stable during the last 20 years; however, currently fewer than 20 are funded through the National Streamflow Information Program (NSIP) of the USGS and the rest rely on funding partners.

In Canada, the majority of climate, hydrometric, and water quality stations are located in the southern half of the country, where the population and economic pressures are greatest. As a result, the adequacy of the network to describe hydrological and climatological characteristics, both spatially and temporally, decreases significantly in the northern part of the country and is particularly poor in the Canadian Arctic Archipelago. There is relatively good information on flows from large rivers (e.g., the Mackenzie and Nelson rivers). However, there is large uncertainty associated with the estimates of ungauged streamflow to the Arctic Ocean, largely due to the paucity of monitoring (Arctic-HYDRA 2010).

The discharge to the Arctic Ocean from Eurasia is better monitored than from North America as most of the river inflow is delivered through a small number of very large rivers with a long history of operating downstream gauges. Only 10 hydrological gauges are sufficient to capture 80% of the total Arctic Ocean drainage area in Russia. Hydrometric observations on small- and medium-sized rivers in the Russian Arctic are sparse and ungauged or poorly monitored areas dominate many parts of the region. Over the last 10 years, the accessibility of river discharge data for the Pan-Arctic has been significantly expanded by the release of the University of New Hampshire's R-ArcticNet database (http://www.R-ArcticNet.sr.unh.edu). However, sharp declines in Russian hydrometric gauging networks in the 1990s and delays in data reporting hamper research progress (Shiklomanov et al. 2002). Since 2000, governmental funding of Russian monitoring networks has improved, and as a result, the number of operating gauges has stabilized or even slightly increased. There are still significant delays in the timely delivery of Russian hydrological data to the international research community and the Arctic Rapid Monitoring System for the Pan-Arctic (Arctic-RIMS, http://rims.unh.edu/) was developed to facilitate and accelerate data reporting for the most important Russian river gauges.

Patterns in the reported decline of monitoring have recently been analyzed to see how they compare with the geographical

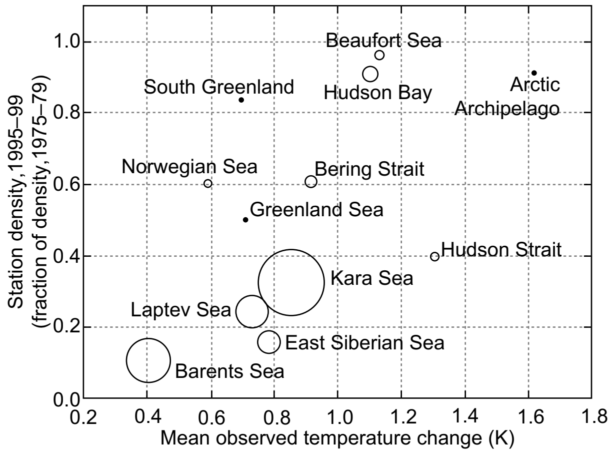

Figure 3 Change in density of hydrological stations in relation to observed temperature changes. Circle sizes correspond to the absolute number of closed stations. Adapted from: Bring, A., and G. Destouni, 2009: Hydrological and hydrochemical observation status in the Pan-Arctic drainage basin. *Polar Res.*, **28**, 327–338.

distribution of observed and predicted Arctic-wide climate. Figure 3 shows how station density has changed since the 1970s, in relation to observed temperature change (Bring and Destouni 2009). The vertical axis is the fraction of stations with accessible data for 1995–99, as a proportion of the stations with accessible data for 1975–79. A fraction of 1 means that the station density is the same today and a fraction of 0.2, for example, means that only 20% of the stations operational in the 1970s still provided data in the 1990s. The horizontal axis shows the mean observed temperature increase during 1995–2002, relative to the 1961–90 average. It is evident that the decline in network density has been greatest for four Eurasian basins. For the Kara Sea drainage, data from 520 stations is no longer available.

Sparse monitoring networks in the northern remote regions are experiencing the most dramatic changes in both climate and land cover. This is precisely the area where there is the most significant gap in existing ground observation networks.

5.11.3 River Streamflow

5.11.3.1 Annual Discharge Variability

There are numerous estimates of the river inflow into the entire Arctic Ocean based on different methods and drainage area calculations. Prowse and Flegg (2000) found the dominant source of variation was drainage area. They compared different geographical definitions of contributing land area to the Arctic Ocean ranging from 13×10^6 km^2 to 24×10^6 km^2 with most of the differences found in how various research groups tended to define the drainage system in North America. They found that river discharge scaled linearly, suggesting comparisons can be made between macroscale geographically varied studies using area normalized runoff.

Observational river data were extensively used to evaluate discharge from the various monitored areas to the Arctic Ocean (Shiklomanov et al. 2000; Peterson et al. 2002; Déry et al. 2005, 2009, 2011). These estimates, however, do not provide information for river discharge to the ocean from extensive unmonitored areas in North America and Eurasia, which are important to understanding the variability of regional runoff and Arctic Ocean freshwater balance (ACIA 2005). There are several different approaches to estimate the runoff from unmonitored areas. In our estimates of river flux to the ocean from the entire drainage area, we applied a combination of the hydrology analogy method (Shiklomanov and Shiklomanov 2003) and runoff simulated from meteorological data using the UNH water balance–water transport model (WBMPlus; Wisser et al. 2008, 2010). The first approach gives good results only if there are monitored river basins representative for regional hydrological, climatic, and land cover conditions. In this case, the runoff data for these rivers can be expanded to the unmonitored territory with similar conditions of runoff formation. Four largest rivers, Yenisey, Lena, Ob, and Mackenzie, contribute about 63% of total gauged discharge (Figure 4).

Unfortunately, in some regions (e.g., Canada's Arctic Archipelago) there are no gauges with regular observations, which could be used as analogs. For these areas we used the hydrological model (WBMPlus) driven with gridded meteorological data (Willmott and Matsuura 2009; Nickl et al. 2010) to estimate the river runoff from the unmonitored area. The simulated runoff was verified and adjusted with observations, if any observational data were available. Estimated river flux to the Arctic Ocean from the entire drainage area ($\sim 19 \times 10^6$ km^2) is approximately 4300 km^3 year^{-1} of which about 2900 km^3 year^{-1} originates from the $\sim 13.0 \times 10^6$ km^2 monitored Arctic land mass. Figure 5 demonstrates annual anomalies of total river flux to the Arctic Ocean from different continents over 1936–2004. The significant increase in river discharge to the Arctic Ocean with a rate of 3.9 km^3 year^{-1} is due to the increased discharge from the Asian (2.2 km^3 year^{-1}) and Northern American (1.2 km^3 year^{-1}) parts of the Arctic drainage basin. River inflow to the ocean from Asia is much better monitored ($\sim$84%) than from other continents. Therefore, uncertainties in estimates of total discharge to the ocean from Asia are much less than from the Europe and Northern America, where unmonitored areas occupy 30% and 65% of total drainage basin respectively (Figure 5).

The Hudson Bay drainage is the only Pan-Arctic sub-continental area where, according to our estimate, the river runoff shows decreasing trends over 1936–2004. Analysis of observational data for 42 rivers flowing into Hudson Bay over 1964–2000 showed a significant reduction of annual discharge equal to 96 km^3 year^{-1} over 37 years (Déry et al. 2005). However, analysis of newer, longer records of discharge to Hudson Bay over 1964–2008 showed no detectable trend with a slightly positive slope of 0.31 km^3 year^{-1} (Déry et al. 2011). The five year running mean in total Hudson Bay streamflow reveals two distinct periods marked by opposite trends. During the first 20 years, mean annual discharge into Hudson Bay decreases, whereas for the most recent 20 years, Hudson Bay streamflow increases sharply (Figure 6).

Eurasia contributes about 75% of the total terrestrial runoff to the Arctic Ocean (Shiklomanov and Shiklomanov 2003) and contains three of the four major Arctic rivers. Observations of combined river discharge from the six largest Russian north flowing rivers (N. Dvina, Pechora, Ob, Yenisey, Lena, and Kolyma) have shown an increase of 7% over the period 1936–99 (Peterson et al. 2002). More recent estimates have shown

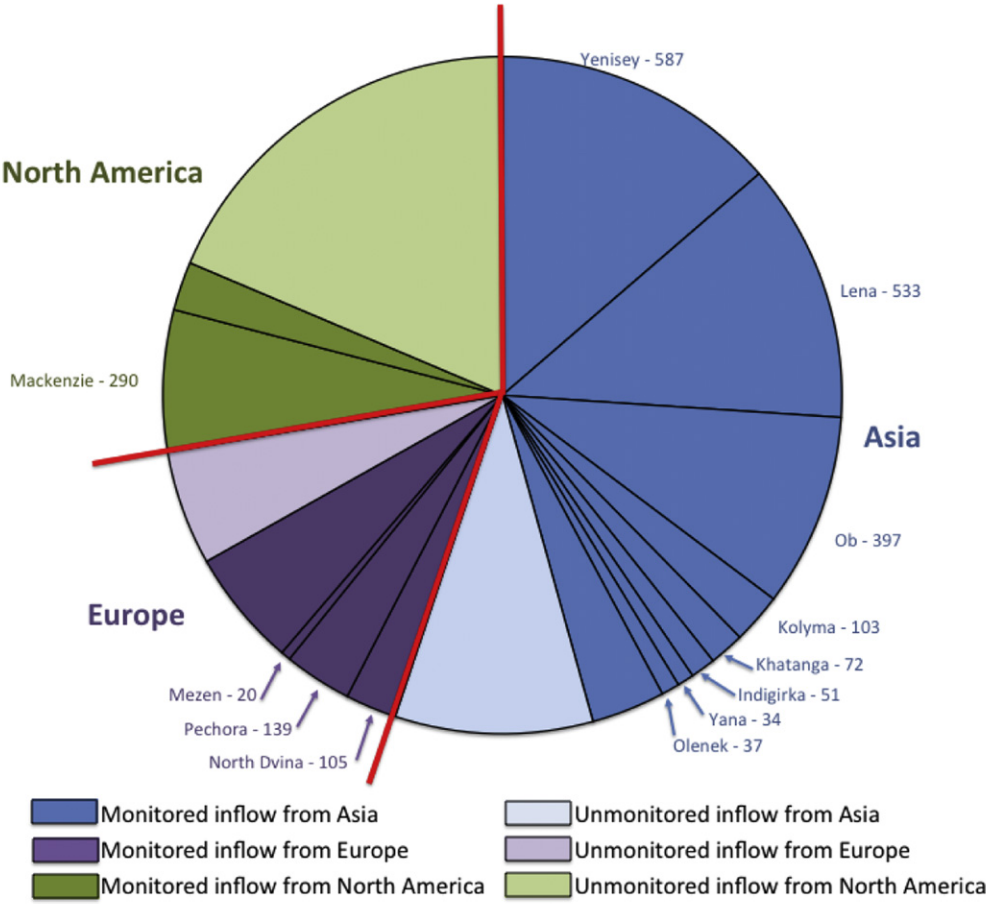

Figure 4 Surface river inflow into the Arctic Ocean from large rivers basins and continents. Source: Arctic-HYDRA, 2010: The Arctic Hydrological Cycle Monitoring? Modeling and Assessment Programme, Science and Implementation Plan. [Available online at http://arctichydra.arcticportal.org/images/stories/Arctic-HYDRA.pdf.] (accessed 21 December 2011).

this increase has continued into the twenty-first century (Richter-Menge 2009; Shiklomanov and Lammers 2009). The mean annual 2000–10 river discharge from the six largest Eurasian rivers was 186 km^3 (10%) higher than the long-term mean over 1936–99 (Figure 7).

Contemporary estimates of the river discharge showed a new historical maximum of the annual discharge to the Arctic Ocean from Eurasia in 2007 (Shiklomanov and Lammers 2009). An especially intensive increase in river discharge to the ocean from Eurasia was observed during the last 20 years, when sea ice extent in the Arctic Ocean has shown a progressive shrinkage (Stroeve et al. 2007). It is interesting to note that the correlation between Eurasian river discharge and sea ice extent over the period of 1979–2008 is $R = -0.72$, or greater than the correlation between runoff and observed precipitation fields aggregated across these Eurasian river basins ($R = 0.54$) (Shiklomanov and Lammers 2009). This suggests that both river runoff and sea ice were responding simultaneously to changes in large-scale hemispheric climate patterns.

There is also an increasing tendency in river discharge to the Arctic Ocean from North America. Figure 7 shows variability of total annual discharge for the four largest North American monitored rivers flowing into Arctic Ocean (Mackenzie, Peel, and Back) and Bering Strait (Yukon) over 1970–2008. The length of discharge records for Arctic rivers in North America is much less than in Eurasia and the increasing trend is not significant. However, the mean annual discharge to the ocean over 2000–08 from these four large North American Arctic rivers was 6% (31 km^3) greater than the long-term mean from 1970–99.

The spatial distribution of runoff across the Pan-Arctic is highly heterogeneous (Figure 8).

The smallest values (less than 10 mm year^{-1}) are found in the steppe regions of West Siberia and Canadian Prairies and the highest values, exceeding 600 mm year^{-1}, can be seen in areas of (1) orographic influence; Norway, the mountainous southern regions of central and eastern Siberia, and along the Alaska Range in southern Alaska and (2) those regions receiving precipitation from cyclonic activity; the European part of the basin, Pacific seacoast of Alaska, and eastern Hudson Bay drainage in Quebec (Lammers et al. 2001). Low runoff semi-arid regions are seen in the southwestern Ob basin, the Selenga basin in northern Mongolia, and the western Canadian Arctic drainage of the Nelson River system. These basins tend to be dry, due to their position on the lee-side of large mountain ranges and their continental climates. The large-scale structure of the

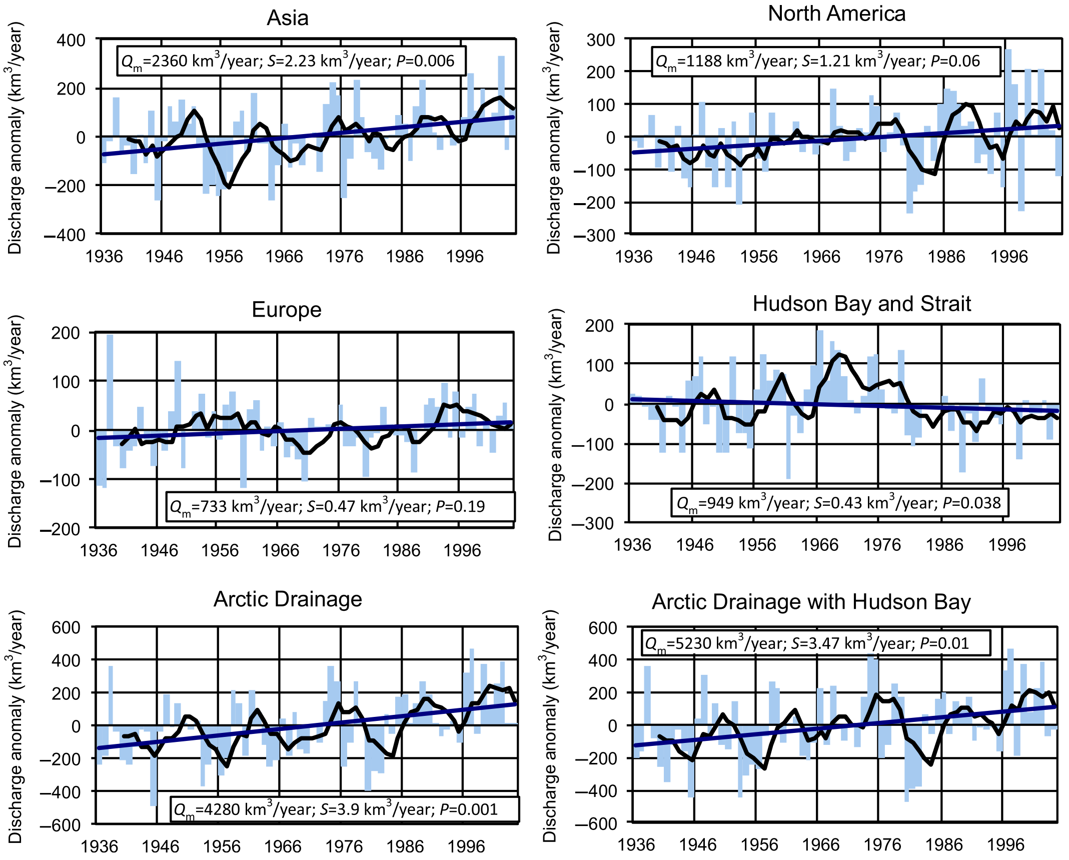

Figure 5 Anomalies of annual river discharge to the Arctic Ocean from different parts of the Pan-Arctic drainage basin over 1936–2004 (blue bars), 5-year moving average (thick black line), and linear trend (thick blue line). Long-term mean annual discharge (Q_m), slope of linear trend line (S), and p-value defining statistical significance of the trend line (P) (updated from Shiklomanov, I. A., A. I. Shiklomanov, R. B. Lammers, B. J. Peterson, and C. J. Vorosmarty, 2000: The dynamics of river water inflow to the Arctic Ocean. *The Freshwater Budget of the Arctic Ocean*, Lewis, E.L., et al., Eds., Kluwer Academic Publishers, the Netherlands, 281–296.).

runoff surface is consistent with the long-term runoff maps given by AARI (1985) and by Fisheries and Environment Canada (1978).

Analysis of discharge variability for the largest monitored individual river basins over the observational periods shows significant positive trends (5% significance level) for the Yenisey, Lena, Pechora, and Severnaya Dvina rivers and no trend for the Kolyma, Ob, Mackenzie, and Yukon rivers. However all large rivers show tendencies toward the increasing discharge (Figure 9). Higher rates of river discharge increases are seen during the period of most intensive air temperature rise (Hansen et al. 2010) over 1980–2008 when all rivers (except the Yukon) show accelerated trend lines (Figure 9). The mean annual discharge of the six Eurasian rivers for 1980–2008 was 100 km^3 or 6% higher than the discharge for the 1936–79 period. As a comparison, this is greater than the annual discharge of the entire Kolyma River, which is the fourth largest Russian north flowing basin.

5.11.3.2 Seasonal Discharge Variability

Knowledge of seasonal discharge variability and change is very important to better understand causes responsible for the dramatic increase in annual river discharge to the Arctic Ocean.

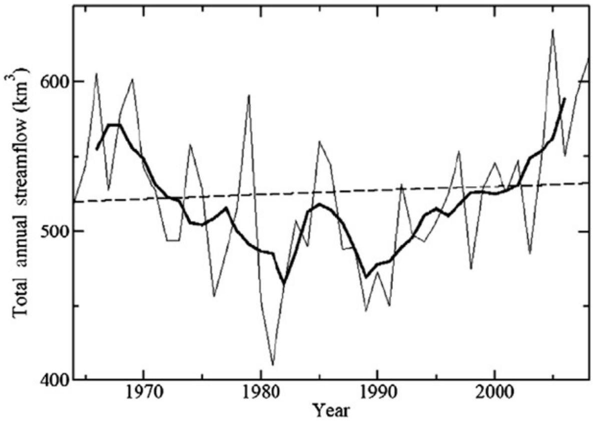

Figure 6 Total annual streamflow into Hudson Bay, 1964–2008 (thin line). A five year running mean (thick line) is shown and the linear trend assessed with Kendall–Theil Robust Line shown for the overall 45-year period (dashed line). Source: Déry, S. J., T. J. Mlynowski, M. A. Hernández-Henríquez, and F. Straneo, 2011: Interannual variability and interdecadal trends in Hudson Bay streamflow. *J. Mar. Syst.*, **88,** 341–351.

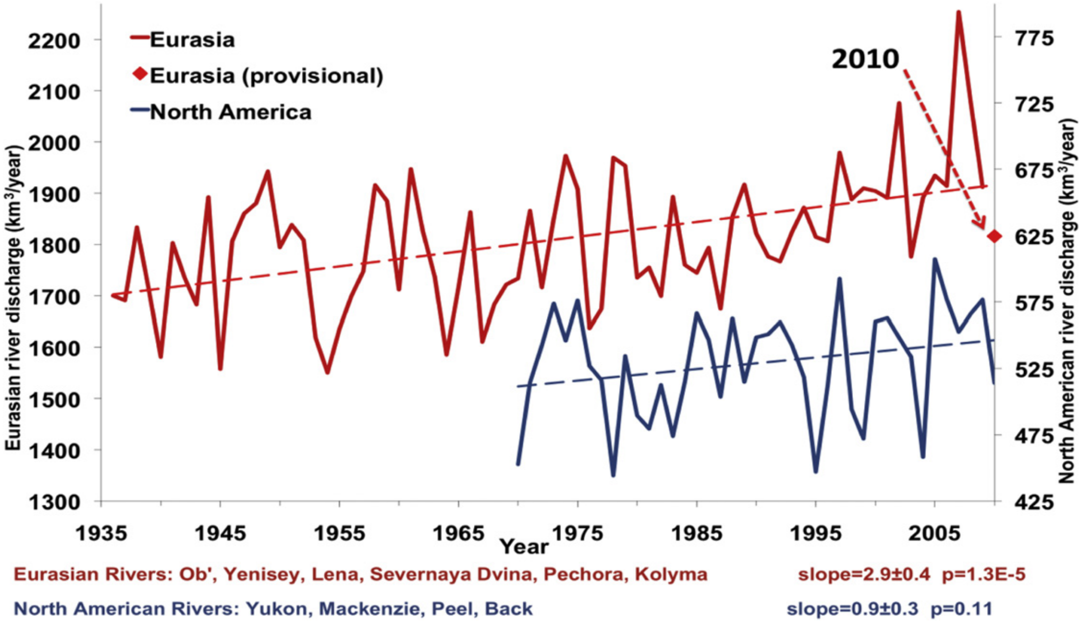

Figure 7 Total annual river discharge to the Arctic Ocean from the six largest rivers in the Eurasian Arctic for the observational period 1936–2010 (updated from Peterson, B. J., R. M. Holmes, J. W. McClelland, C. J. Vorosmarty, R. B. Lammers, A. I. Shiklomanov, I. A. Shiklomanov, and S. Rahmstorf, 2002: Increasing river discharge to the Arctic Ocean. *Science*, **298**, 2171–2173, 13 December 2002.) (red line) and from the four large North American Pan-Arctic rivers over 1970–2010 (blue line). The least squares linear trend lines are shown as dashed lines.

In addition to climate-induced river streamflow variations, water management such as construction of large reservoirs, inter-basin water diversions, and water withdrawals for various needs can significantly impact river discharge variability (Shiklomanov and Lammers 2009; Ye et al. 2003; Yang et al. 2004; Vörösmarty et al. 1997). However, human influence on the hydrological regime of Pan-Arctic rivers is usually considered to be minor in comparison with mid to low latitude rivers, due to lower population, severe natural conditions, and scarce development (Vörösmarty et al. 1997; Lammers et al. 2001). Water consumption for human needs in large Pan-Arctic River basins do not exceed 1–1.5% of total river discharge and do not significantly affect annual variability of river discharge to the Arctic Ocean (Shiklomanov and Shiklomanov 2003). At the same time, engineered control of streamflow as the result of reservoir regulation is very important for many large Arctic rivers. The construction of dams and reservoirs in river systems has the effect of changing the timing of river flow. At higher latitudes, the impoundments are primarily used for hydroelectric power generation and storing water for dryer summer seasons. Thus, they redistribute water between the seasons and can significantly change the seasonal hydrological regime reducing peak discharge during spring and early summer and increasing discharge during low-flow periods. This effect on seasonal hydrology is widely documented for the Ob, Yenisey, Lena, and Mackenzie rivers (Ye et al. 2003; Shiklomanov and Lammers 2009; Berezovskaya et al. 2005; Adam et al. 2007). The results for these basins demonstrate that reservoir effects can exceed climate-induced hydrological changes even in downstream gauges remotely located from reservoirs. In addition to seasonal discharge distribution, large dams may also affect yearly flow characteristics at the basin scale, particularly during reservoir filling periods immediately after dam construction (Stuefer et al. 2011; Yang et al. 2004; Shiklomanov and Lammers 2009). Thus, to analyze the climate-induced long-term variability of seasonal discharge to the Arctic Ocean associated with climate and to better understand the physical mechanisms driving the observed changes in seasonal discharge, it is necessary to eliminate the direct human impact from the observed streamflow records.

We developed Hydrograph Transformation Model (Shiklomanov et al. 2011) to eliminate reservoir effects from observational hydrographic data and applied it to the three largest Pan-Arctic River basins – Yenisey, Lena, and Ob. The linear model with concentrated parameters is based on routing of daily discharge hydrographs from the unregulated part of the basin along the river network to the downstream river gauge. The optimal parameters for the model are evaluated from the minimization of mean square deviation between the observed and simulated daily discharge values over the pre-dam period. The model has shown less than 10% mean relative errors of modeled daily discharge from observations over the pre-dam period, which are comparable to the accuracy of daily discharge observations on large Siberian rivers (Shiklomanov et al. 2006) (Figure 10, left panel). Simulations of natural streamflow regime during the post-dam period are made consequently from upstream to downstream using the routing parameters defined over the pre-dam period. The effect of reservoirs on river discharge can be seen clearly at the river gauge on the Yenisey River at Bazaikha, where the strong spring snowmelt pulse has been completely eliminated (Figure 10, right panel) by the construction of the massive Krasnoyarsk dam and reservoir on the main stem of the Yenisey River (Shiklomanov and Lammers 2009). With the additional flow of multiple large tributaries into the Yenisey River, these severe effects are attenuated downstream and once the last downstream gauge (Igarka) is reached the overall effect of impoundments is significantly decreased.

Figure 8 Long-term average annual gridded runoff surface climatology (January 1979 – December 2011) is highlighted for the Pan-Arctic. Map based on runoff simulations of UNH water balance model (WBMPlus) (Wisser, D., B. M. Fekete, C. J. Vörösmarty, and A. H. Schumann, 2010: Recon-structing 20th century global hydrography: a contribution to the Global Terrestrial Network- Hydrology (GTN-H). *Hydrol. Earth Syst. Sci.*, **14**, 1–24.) driven with NASA Modern Era Retrospective analysis for Research and Applications (MERRA) re-analysis (Rienecker, M. M. and Coauthors, 2011: MERRA – NASA's Modern-Era Retrospective Analysis for Research and Applications. *J. Clim.*, **24**, 3624–3648, http://dx.doi.org/10.1175/JCLI-D-11-00015.1.). The MERRA driven runoff simulation has a good agreement with high latitudes observational discharge (Shiklomanov et al. 2011).

Analysis of annual and seasonal observed and naturalized (modeled) river discharge for downstream river gauges showed that at annual time steps the trends are less impacted by dam construction, whereas seasonal discharge variability is strongly confounded by both climate variability, human impact, and the climate signals are often overwhelmed by the human-induced disturbances in river discharge.

Combined analysis of observed and naturalized discharge for the six largest Eurasian Pan-Arctic rivers (Kolyma, Yenisey, Lena, Ob, Severnaya Dvina, and Pechora) showed that there is a significant difference in seasonal discharge trends estimated from observed and naturalized data. Based on observations the annual discharge increase is mostly due to an increase of winter (~70%) and spring flows (~25%). Naturalized discharge records show similar trends in annual discharge accompanied with streamflow increases in spring (account for 49%), winter (account for 31%), and summer-fall (account for 20%) (Figure 11).

Similar results for changes in seasonal discharge across the Eurasian Pan-Arctic were obtained based on river flow data for small- and medium- sized rivers. Shiklomanov (2008) analyzed monthly discharge records longer than 50 years from 75 gauges in the Russian Pan-Arctic. The analysis considered only those rivers for which there has been no significant human impact on the hydrological regime. The mean seasonal discharge over the period 1978–2005 was compared with mean discharge over the period 1946–77 (Figure 12). A prevailing pattern of year-round discharge increases across most of Northern and Eastern Siberia, and winter increases across the entire Russian Pan-Arctic was found (Figure 12(a)). Winter runoff has increased by as much as 40–60% in the Irtysh basin, a tributary of the Ob in South-eastern Siberia, and by as much as 15–35% in Northern Siberia. Additionally, significant increases were found in summer-fall runoff in the Irtysh and Tobol basins (25–40%) and in Eastern Siberia (10–25%) (Figure 12(c)). Spring runoff also demonstrates an increase with the most significant values in Western and Eastern Siberia (Figure 12(b)).

Thus, seasonal discharge records aggregated for large river basins and small–medium sized watersheds show similar tendencies over the long-term period. All seasons contributed to the increase in annual discharge to the Arctic Ocean and it likely results from multiple causes. The increase in volume of spring

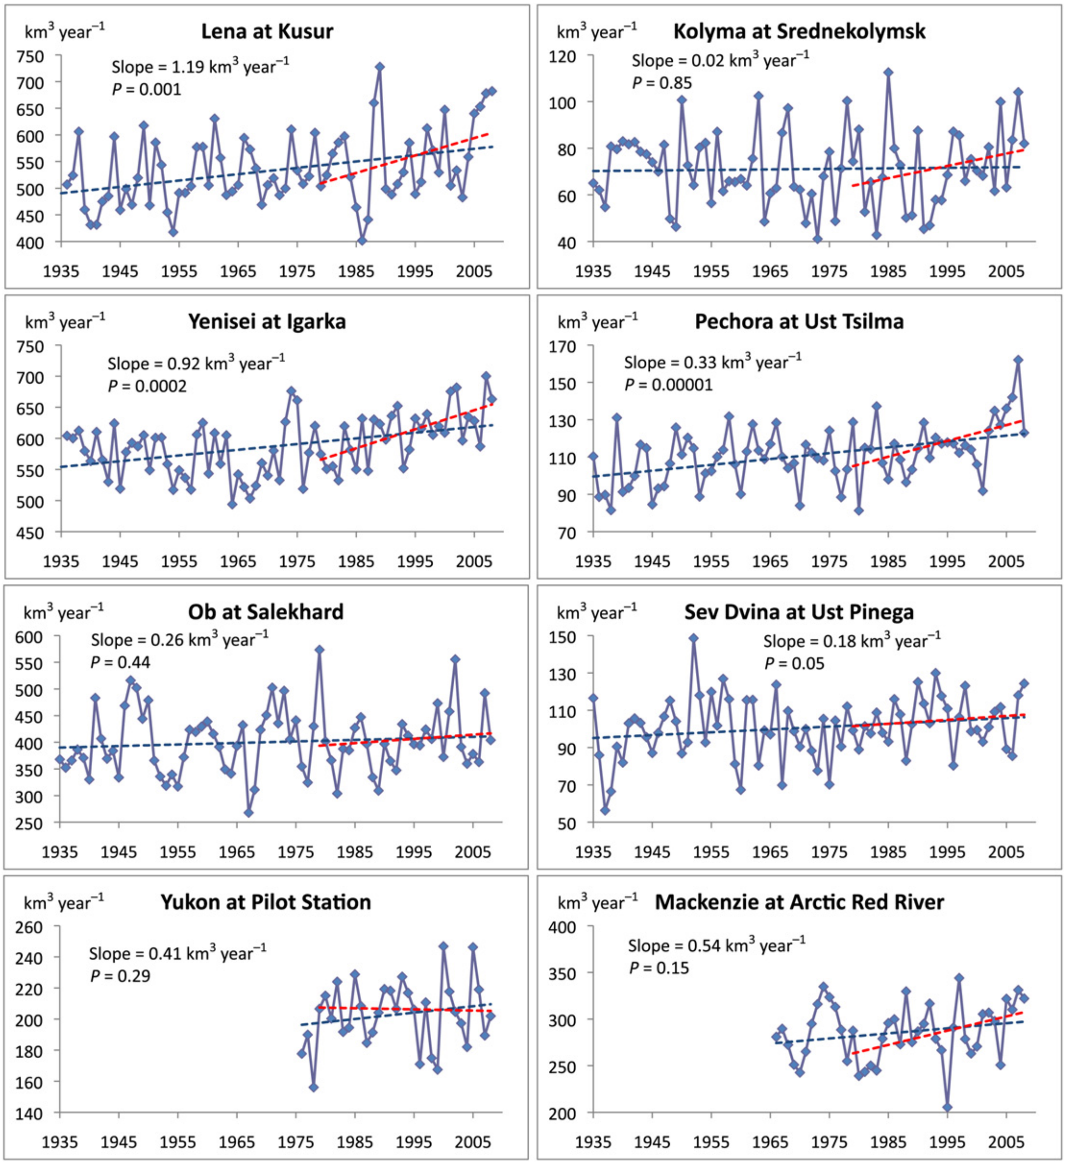

Figure 9 Annual discharge variations for the eight largest monitored Pan-Arctic rivers over the periods of observations. Dashed lines show linear trends for entire observational periods (blue) and for 1980–2008 (red). Updated historical data from the R-ArcticNet river discharge archive (http://www.R-ArcticNet.sr.unh.edu) were used for the graphs. Some gaps in the discharge records were reconstructed using information from upstream gauges.

discharge is supported by increases in cold season precipitation reported in several publications (Rawlins et al. 2006, 2010). The rise of winter, summer, and fall runoff is probably related with mobilization of subsurface water activity due to permafrost thawing, decreased winter freezing of soils and winter snowmelt events caused by warmer winters and deeper snowpack (Smith et al. 2007). A more deeply thawed, or more frequently thawed, landscape would not only accept more infiltration from the surface, but also shift water storage from the surface–near-surface to greater depths, reducing evapotranspiration water losses to the atmosphere (Smith et al. 2007).

Changes in precipitation are usually considered as the primary cause of any alteration to the hydrological regime and this is often the default assumption (McClelland et al. 2004). A comprehensive analysis of precipitation and river runoff was subsequently carried out using several long-term precipitation data sets (Rawlins et al. 2006; Shiklomanov et al. 2007) and river discharge from R-ArcticNet (Lammers et al. 2001; Shiklomanov and Lammers 2009). Annual snowfall across the Eurasian Pan-Arctic exhibited a strong significant increase from 1936 to the late 1950s and a moderately significant decrease thereafter. Due to spatial variation, an integrated signal across northern drainage basins yielded no significant change in annual precipitation. Berezovskaya et al. (2004) suggested that either the existing precipitation products were unable to capture high-latitude precipitation changes, or some other processes were responsible. Summer-fall precipitation, which controls soil and groundwater storage before freeze over,

showed declines (Rawlins et al. 2006; Berezovskaya et al. 2004) and presents an offsetting trend to the well-documented increases in fall–winter runoff.

In contrast to precipitation, the significant increase in air temperature across the North Eurasian Pan-Arctic has been widely and consistently documented (e.g., Hansen et al. 2010) and it is expected to continue with higher rates in future (ACIA 2005). The warming of the Pan-Arctic has already led to significant changes in land cover (Gutman and Reissell 2010). Thawing of permafrost (Brown and Romanovsky 2008), changing soil freeze–thaw cycle (McDonald et al. 2004), reductions and disappearance of wetland–natural lake areas (Smith et al. 2005), thinning river ice and glacier retreat (ACIA 2005), as well as, changes in vegetation structure (Zhou et al. 2003) may have significant impacts upon the hydrological regime and river discharge even without noticeable changes in precipitation.

5.11.3.3 Extreme Discharge Variability

Maximum river discharge often results in flooding. Future climate model projections suggest that the frequency and magnitude of extreme hydrological events, including floods, would increase at high latitudes in response to climate change (IPCC 2007). Shiklomanov et al. (2007) analyzed long-term variability in maximum daily spring discharge for 139 small- and medium-

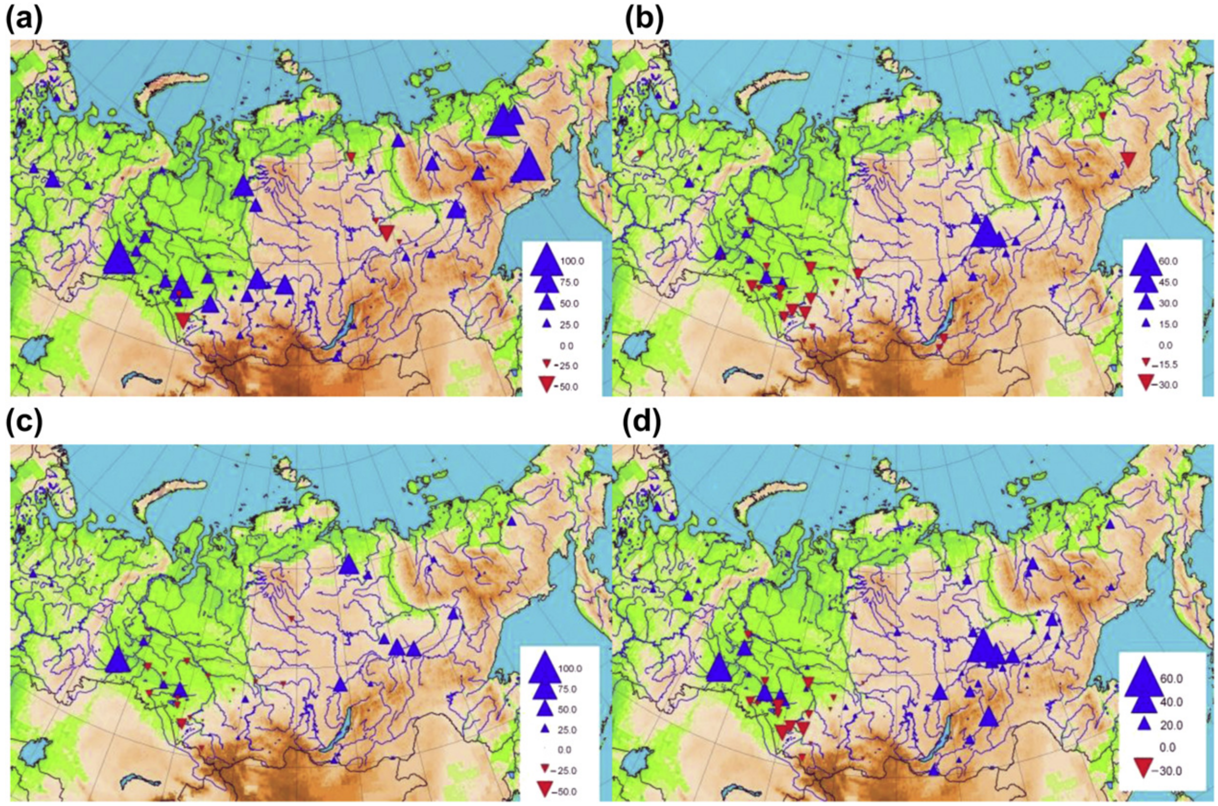

Figure 12 Anomalies of winter (a), spring (b), summer-fall (c), and annual (d) runoff across the Russian Arctic Ocean drainage basin for 1978–2005 (in % relative to 1946–77). Source: Shiklomanov I. A., Ed., 2008: *Water Resources of Russia and Their Use*. Nauka, St. Petersburg, 598 pp. (in Russian).

sized Russian rivers (16–50 000 km^2) with minimal human impact. Trend analyses were applied to the magnitude and timing of maximum spring discharge values over the periods 1960–2001, 1950–2001, 1940–2001, and 1930–2001 using both least squares linear regression and the more robust, nonparametric Mann–Kendall test (Helsel and Hirsch 1992). All rivers had clearly pronounced spring peaks in April–June.

Relative changes in spring maximum discharge for different periods are shown in Figure 13. There are approximately the same number of gauges with both positive and negative changes for all time periods. The number of gauges, with significant positive and negative trends, are similar for 1960–2001 and 1930–2001, and there are slightly more gauges with significant negative trends for 1950–2001 and 1940–2001. Overall, we find no widespread significant changes in trends of spring maximum discharge across the Russian Arctic drainage basin. However, there are several regions with common patterns in maximum discharge change. Significant decreasing tendencies are noted across the south of central siberia and far east (regions 2 and 4 in Figure 13). The change in spring maximum discharge in these regions coincides with trends in cold season precipitation, which mostly generates spring peak flow. The Lena River basin and North European Russia (regions 1 and 3 Figure 13) showed significant increases in maximum discharge. There was no uniformity between changes in precipitation over the cold period and maximum discharge. This discrepancy leads us to suspect that other factors were responsible for discharge changes across these regions.

Maximum river discharge is usually associated with floods, which cause more damage in Russia than any other natural disaster. We recognize, however, that maximum water level, which results in out of bank flow does not always conjoin with maximum discharge, owing to the backwater effects and ice damming in rivers. Recent estimates of extreme water levels, to characterize the flood situation across Russia, showed the greatest increase in water level peaks in south central siberia and the far east (Shiklomanov 2008) where spring peak discharge is decreasing (Shiklomanov et al. 2007). About 50% of river gauges in these regions showed 10–75% increase in maximum water level over 1981–2005, but the ice damming was a main cause of extreme floods.

Minimum discharge is an important characteristic of water availability. Due to the extreme seasonality, Arctic runoff is highly variable throughout the year and inspite of relatively high annual runoff many rivers in high latitudes can dry out or freeze over during certain periods creating difficulties for water supply. The minimum discharge is most sensitive to groundwater and/or unsaturated zone water inputs and its volume characterizes changes in subsurface water contributions to the river. Smith et al. (2007) analyzed the same Russian time series as Shiklomanov et al. (2007), discussed above, to examine daily discharge minima. They found that the increases in minimum daily discharge were more abundant than the decreases, leading

them to suggest this as sole factor contributing to the overall rise in Russian river discharge to the Arctic Ocean. There was no coherent spatial pattern to these increases. However, Smith et al. (2007) acknowledged these increases in later years in minimum flow involved a small number of gauges ($n \leq 10$) with a very different spatial distribution of gauges than the other time periods. As a result, they tested the hypothesis of accelerating Arctic hydroclimatology by selecting a small subset of data with very long records covering the period 1935–2002. They looked at monthly anomalies in daily minimum discharge (**Figure 14**) and found increases in the long-term records from approximately 1985 onwards for the months November to April and for all months since 2000. Additionally, during the last few years of the time series, 9 of 12 months showed magnitudes at or near record levels (**Figure 14**). Overall, they found no unique role for permafrost contributions to minimum daily flow, yet the observed signal does suggest a 'thawlike process'. This indicates a much more complicated set of interactions between climate, evapotranspiration, infiltration, thawing lakes, groundwater, and permafrost processes.

5.11.4 Discussion and Conclusions

The hydrological regime of Pan-Arctic rivers has undergone dramatic changes in the last few decades, but the causes responsible for these changes are not fully understood. River discharge as an integrated characteristic of numerous geophysical processes and as one of the most accurately measured components of water cycle is very important for tracking and understanding of environmental changes at high latitudes. However, despite the value of discharge information, ungauged or poorly monitored areas dominate many parts of the Pan-Arctic and recent declines in Russian and Canadian hydrometric station networks, and some restrictions and delays in the dissemination of data, especially for Russia, obstruct research progress. There is therefore a clear need to establish an integrated, international operational system for the monitoring of Pan-Arctic hydrology.

According to most contemporary assessments the total discharge to the Arctic Ocean is approximately 4300 km^3 $year^{-1}$ and continental contributions to the river input into the Arctic Ocean for Asia, North America, and Europe are 55%, 28%, and 17% respectively. Total river discharge to the Arctic Ocean has shown a significant increase over 1936–2004 with a mean linear slope of 3.9 km^3 $year^{-1}$ and all continents contribute to this increase. The Hudson Bay drainage basin is the only Pan-Arctic sub-continental area where according to our estimate the river discharge shows decreasing trends over 1936–2004. Discharge from the monitored part of the Pan-Arctic drainage is increasing even more intensively with an extremely significant increase of Eurasian river flow. The total increase in the discharge of six largest Eurasian rivers flowing to the Arctic Ocean (N. Dvina, Pechora, Ob, Yenisey, Lena, and Kolyma) over 1936–2010, computed based on linear trend, was approximately 210 km^3 or equivalent to the Yukon River discharge.

Using newly 'naturalized' (without local human impact) river discharge data for the great Siberian rivers, we found that this dramatic increase in annual discharge is the result of changes during all seasons and this assumes multiple causes of additional contributions to streamflow. Especially noticeable were relative increases in river discharge found during the winter period when high-latitude river runoff is minimal. Many rivers demonstrate more than 100% discharge increase in winter, pointing out the mobilization of subsurface water activity at high latitudes.

Thus, we conclude that the hydrological regime of rivers across the Pan-Arctic is strongly intensifying producing more and more freshwater input to the Arctic Ocean. Such changes in river flux, along with thawing of sea ice, and increasing precipitation over the ocean may exert significant control over the North Atlantic meridional overturning (thermohaline) circulation. This is significant for global ocean circulation by controlling the volume of North Atlantic deep water formation with potentially dramatic consequences for climate in the Northern Hemisphere. Accordingly, to project possible extreme anomalies and better adapt to ongoing and oncoming environmental changes we should expand our knowledge and understanding of these hydrological alterations.

To better understand the physical mechanisms driving the hydrological changes at high latitudes, it is necessary to (1) extend the regional experimental investigation on interactions between ground and surface water, especially in the permafrost and transition zones; (2) extend our *in situ* monitoring networks, especially in currently unmonitored rivers, and improve international collaboration in data exchange; (3) expand the scale of remote-sensing monitoring efforts; and (4) improve representation of physical processes at different scales in hydrological models. These four elements are interrelated and the best progress can be reached if development will simultaneously involve all these fundamental pieces.

5.12.1 Introduction

For two millenia, water power has been an important energy resource in regions of the world that boast the requisite characteristic of ample streamflow coupled with sufficient hydraulic head (elevation gradient). One of the earliest applications provided energy for milling grain, using waterwheels driven by the weight of falling water (Greece, *c*.100 BC; cf. http://en.wikipedia.org/wiki/Water_wheel), a practice that spread to Europe and Asia as early as the first century AD. The earliest example of a turbine-like water mill implementation dates to third or fourth century AD at a site in modern day Tunisia. Along with the sail, use of water for milling is the earliest example of a machine harnessing natural forces to replace human labor.

The use of water wheels for power continued for the next 2000 years, but their size and weight limited the flow and head that could be converted into power. During the industrial revolution of the nineteenth century, these limitations were overcome by new materials, manufacturing capabilities, and scientific and engineering methods that ushered in a range of turbine designs to enable far larger projects. This technical development set the stage for rapid growth and expansion of the hydropower industry in the twentieth century, leading to a global installed capacity of 1000 GW of hydroelectricity as of 2010, or about 24% of the world's electricity.

Since the rise of the environmental movement in the 1970s, however, hydropower development in many first-world nations has largely ceased. Today, initiatives to remove old dams (including marginal hydropower facilities) have gained the following. Dam removals have been primarily motivated by interest in restoring watershed habitats to support fisheries and, in regions such as the US Pacific Northwest (PNW), the local cultural heritage associated with salmonids. Additional concerns over the outlook for hydropower are rooted in the

http://dx.doi.org/10.1016/B978-0-12-384703-4.00514-1

findings of several decades of research characterizing the effects of low-frequency climate variability and possible future climate change on hydrology. North American midlatitude climate has warmed significantly in the past 30 years, leading to reduced snowpack, earlier runoff, and diminished spring and summer streamflows, as well as a possibility of greater extremes in flooding and drought. Although reservoir-based hydropower is designed to manage flow variability, hydroclimatic variability of this type undoubtedly has potential to impact hydropower generation and operations. The western US drought of the 2000s, for instance, substantially reduced Colorado River reservoir storage (Lakes Powell and Mead), leading to reductions in hydropower generation of up to 30%. Potential climatic change impacts and fears over energy security also spur concerns over the sustainability of thermal generation practices, driving interest in renewable energy development that includes, to some extent, hydropower.

The combination of potential climate-related impacts and continued environmental pressure on hydropower motivates this chapter, which assesses the sustainability of hydropower in the twenty-first century. The chapter has three major thematic parts. The first (see Section 5.12.2) describes the basic physics of hydropower, its range of implementation, and history of growth. The second part (see Sections 5.12.3 and 5.12.4) discusses challenges for hydropower, including environmental and social concerns, as well as the regulatory environment. The third part (see Sections 5.12.5 and 5.12.6) describes two issues that are potential drivers for change in the hydropower industry: the growth of renewable energy and nonstationarity. The term 'nonstationarity' is used here in the water resource engineering and management context described by Milly et al. (2008) – that is, reflecting concern that sample statistics describing weather and streamflow deduced from available historical records are not sufficient to capture true population statistics in light of various forms of low-frequency variability or longer term trends in system behavior. The chapter concludes with a discussion of the implications of the issues highlighted in earlier sections for the sustainability of hydropower. The PNW region of North America serves as the chapter's focus, but many of the factors discussed apply, in varying degrees, to hydropower elsewhere in the world.

5.12.2 Harnessing Hydropower: An Overview

5.12.2.1 Extracting Energy from Water

Modern hydropower plants are generally divided into storage projects, which have a reservoir large enough to detain or regulate runoff significantly, and *run-of-river* projects, which may have a weir and pondage (i.e., small storage relative to flow) but generally not an appreciable storage; thus they must pass inflows and cannot buffer their variability. Within these categories of projects, power generated by a wide range of devices and associated facility designs. A factor commonly used to discriminate between types of devices and projects is the amount of hydraulic head, or the water's potential energy, available, given the project location and design. The most productive, typically large reservoir projects often make use of medium- to high-head turbines, whereas many run-of-river projects use low- to medium-head turbines. In a reservoir project, as illustrated by the schematic of Figure 1, the hydraulic head is developed from the difference in the reservoir surface elevation and the project tailwater elevation.

Hydroelectric plants that extract energy both from the flow rate of the water and its pressure or hydraulic head generate power according to the expression

$$P = k\rho\phi gh$$

where ϕ is the flow rate of water, h is the hydraulic head, g is the acceleration due to gravity, ρ is the density of water, and k is a coefficient of efficiency determined by the type of turbine, facility design, and the dynamic flow and head conditions at which the turbine is operated.

Power extracted by waterwheels and other hydrokinetic devices having negligible head depends primarily on the flow rate of the water passing over, under, or through them. Thus the power generated is proportional to the water's kinetic energy, which can be calculated using the expression

$$P = ½\rho A v^3$$

where P is the power, ρ is the density of water, A is the cross-sectional area of the flow, and v is the water velocity.

Medium- to high-head projects, especially in relatively low-flow regimes, often employ *impulse* turbines, in which the water is directed through the air at high velocities onto the turbine blades by jets that leverage the substantial water pressure (contributed by the head). Low- to medium-head projects and those with the highest flows (which require less head to generate acceptable power as a result) commonly use *reaction* turbines, in which the turbine blades are fully immersed in water and enclosed in a pressured casing. The pressure differences across the blades create lift forces that drive the rotation of the runner. Widely used turbine types operating in these flow and head regimes are the Kaplan (for heads between 2 and 40 m; dating to 1913) and Francis (for heads between 10 to 350 m; dating to 1849) reaction turbines and the Pelton (50–1300 m) impulse turbine, although a number of alternative or derivative designs exist. Figure 2(http://en.wikipedia.org/wiki/File:Water_Turbine_Chart.png) illustrates the approximate ranges for head and flow ranges for which particular turbine types are appropriate.

5.12.2.2 Hydropower across Scales

That both axes of Figure 2 are logarithmic indicates the remarkable variation across scales and conditions for which hydropower devices can be applied. The largest hydropower plants generate more energy than any other type of power-producing facility (Three Gorges Dam at 22.5 GW, Itaipu Dam at 14 GW, and Guri Dam at 10.2 GW), whereas the smallest may power only a portion of the energy needs of a single home. The uses, benefits, impacts, and prospects of hydropower across these scales differ substantially.

5.12.2.2.1 Large Hydropower

The scale classifications of hydropower are approximate and vary regionally, but facilities from over 50 MW up to those exceeding 10 GW are generally described as large hydropower. These facilities require massive infrastructure, including large

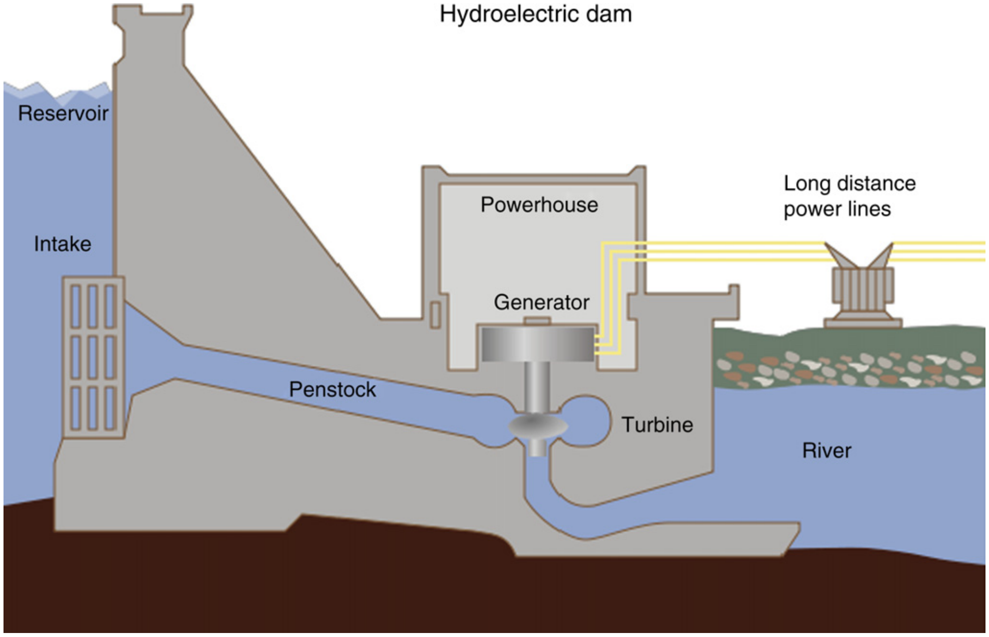

Figure 1 Schematic of a hydroelectric dam. Courtesy of http://en.wikipedia.org/wiki/File:Hydroelectric_dam.svg.

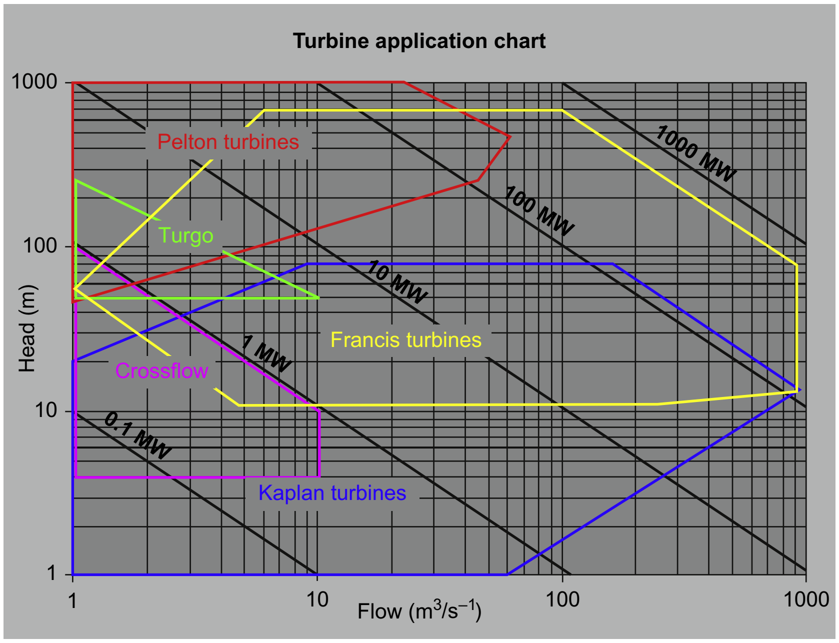

Figure 2 Head and flow range guidance for turbine application.

dams, large storage capacity, and large transmission lines, and their construction and operation typically cause large-scale multifaceted impacts in their watersheds and to the hydrologic cycle of the river that they regulate. Most are multipurpose facilities, and in some cases, hydropower generation is not the primary operational purpose. For example, the major projects in the PNW have traditionally been managed synergistically to support navigation, flood control, river and lake recreation, fisheries and other habitat protection, agricultural irrigation, municipal and industrial electricity demand, as well as hydropower. Such joint operations constrain both current power generation and the options available for power operations to adapt to future changes in energy demands or inflow variability. Owing to the cost of their construction and the multiplicity of stakeholders in such projects, most projects (although not all) in North America are owned by governments, typically in the form of federal agencies in the United States or provincial Crown corporations in Canada.

A useful hydropower system configuration often associated with large-scale plants, but also appearing in smaller, stand-alone forms is *pumped storage*, in which water can be moved between reservoirs at different elevations. At times of low electrical demand, excess generation capacity is used to pump water into the higher reservoir so that water can be released back into the lower reservoir (through a turbine) at times of higher demand. These systems are net consumers of energy, since they do not regain the energy lost in pumping water upward while generating. Yet pumped storage schemes provide a highly flexible, thus, important means of large-scale grid energy storage and serve to 'firm' the capacity of other energy generation systems to which they are linked. Energy that power systems can produce reliably is termed *capacity* and is far more valuable than energy that can be produced intermittently. Energy storage can smooth out the intermittency of resources that do not always generate, creating additional capacity, in a process called firming.

5.12.2.2.2 Small Hydropower

Hydropower is considered small if the capacity is less than 10 MW, although in regions such as the United States and Canada, the category includes capacities of up to 25 MW. Many small-scale hydropower plants are also multipurpose, although less frequently so than large-scale plants, and typically serve a community or localized industrial purpose. Many small hydro projects are run-of-river plants, in which a portion of the flow is diverted from a steep-gradient river and returned with high head through turbines farther downstream, while passing the remaining flow for environmental purposes. Environmental and social impacts generally scale with project size (e.g., storage, civil works, although this is not always the case: poorly designed projects can have impacts that are disproportionate to their scale, and this decreased environmental impact depends strongly on the balance between stream flow and power production. Thus small hydro projects have new expansion potential in some developed countries where new large-scale plants are infeasible.

Small-scale hydroelectricity production grew by almost 30% from 2005 to 2008, including 3 GW of new capacity in the United States (Renewables Global Status Report 2006 Update, REN21, published 2006). Although small projects, and particularly 'low-power' (<1 MW) projects, far outnumber and have greater new development potential than large hydro projects, they also make up far less of the aggregate capacity. **Figure 3**, which summarizes large, small, and 'low power' (<1 MW) projects in the United States, shows that it would take about a 50% increase in small hydropower to offset a 5% decrease in large-scale capacity. Small hydro developers may benefit in overcoming opposition to new projects by earning a certification of 'low impact' from various groups attempting to promote such a standard. The requirements may include impact criteria in the areas of river flows, water quality, fish passage and protection, watershed protection, threatened and endangered species protection, cultural resource protection, and recreation and existing infrastructure (see, e.g., http://www.lowimpacthydro.org/).

5.12.2.2.3 Micro, Pico, and Hydrokinetic Power

Smaller forms of hydropower exist, particularly for rural electrification purposes, in third world countries, or for reaching locations that are remote from any power grid or transmission. Categories include pico hydropower (<5 kW) and micro hydropower (<100 kW). These forms can provide power to an isolated home or a small community, or are sometimes connected to electric power networks. Many systems are run of river, with negligible pondage. Hydrokinetic technologies ranging from a few kilowatts to <500 kW represent a growth area in the United States. In late 2008, the City of Hastings, MN, installed the United States' first-ever commercial, federally licensed hydrokinetic power station, a 250-kW turbine located in the tailrace of a 4.4-MW US Army Corps of Engineers project. Only 2400 of the nation's approximately 80 000 dams have installed hydropower capacity, and many also provide streamflows through irrigation ditches and other infrastructure. Because the civil works for many of these sites exist and the hydrokinetic devices more easily meet low-impact standards, the US hydropower industry envisions a spread of devices, although the overall impacts on US capacity may be small. Offshore hydrokinetic energy in the form of wave or tidal power also holds potential for future hydropower growth. Wave technologies are newer and more experimental than tidal technologies, which now support local energy supplies in countries such as Canada and Scotland.

5.12.2.3 The Historic Growth of Hydropower

Hydropower advocates cite numerous benefits relative to other forms of electricity generation. Over 2000 hydroelectric power plants in the United States currently supply approximately half of the nation's renewable electricity (http://en.wikipedia.org/wiki/Hydroelectricity–cite_note-REN21-2011-0). Like other renewable energies, hydropower generation avoids carbon dioxide emissions that are a by-product of thermal generation: the 250 TWh of hydroelectricity generated in the United States per year, for instance, would emit 243 million metric tons of carbon dioxide, or about 3.5% of the US total emissions. This estimate assumes approximately 7 billion metric tons per year (http://en.wikipedia.org/wiki/List_of_countries_by_carbon_dioxide_emissions), 10 296 Btu/kWh for fossil-fueled steam-electric plants, 207.7 lb of CO_2 per million Btu (EIA, Annual Energy Review, 1995), and 250.6 TWh of hydroelectric generation per year (http://en.wikipedia.org/wiki/Hydroelectricity), if produced by a coal-fired steam plant. Unlike other fuels, hydropower that is integrated into a multipurpose reservoir project can also subsidize secure water supply, irrigation for food production and flood control, and societal benefits such as increased recreational opportunities and improved navigation. Hydropower is one of the cheapest and most efficient energy sources, and the fuel (streamflow) is not subject to market price variation. One of the most important benefits of hydropower is that, as a form of energy that can be ramped up or down quickly and also stored, it almost uniquely provides important additional services to electricity networks (discussed further in Section 5.12.5).

Nonetheless, in retrospect, the twentieth century bracketed the major period of hydropower development, with early generators having been installed near the turn of the century and steady growth in new capacity occurring until the 1970s (**Figure 4**). For example, in 1920, 40% of the US electrical supply came from hydropower. Hydroelectric generation is by

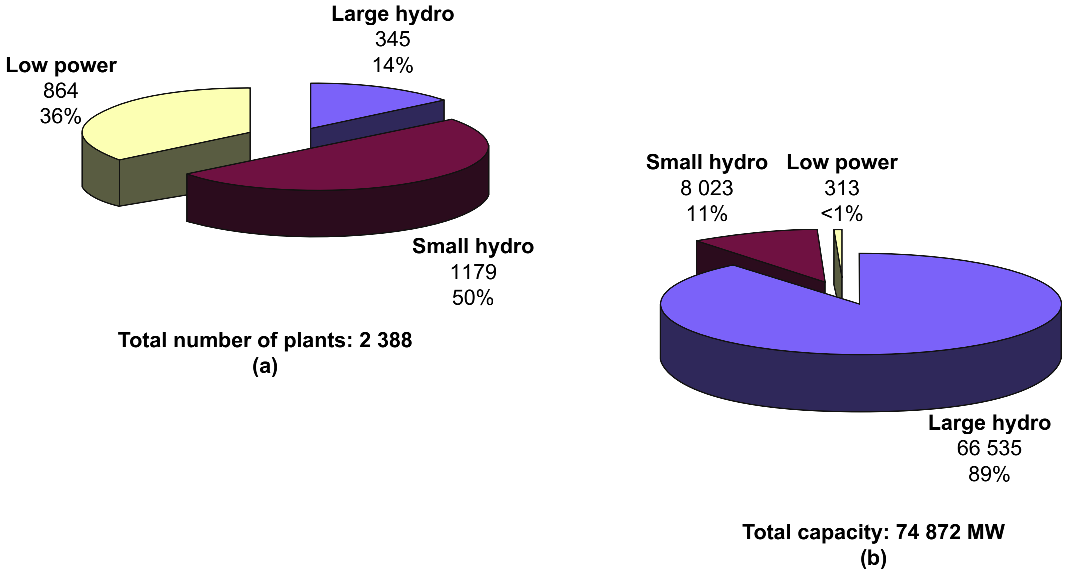

Figure 3 Distribution of US hydroelectric plants by power class in terms of (a) number and (b) total power class capacity (Hall, D.G., and K.S. Reeves, 2006: *A Study of United States Hydroelectric Plant Ownership*, Idaho National Laboratory, US Department of Energy, Idaho Falls, INL/EXT-06-11519).

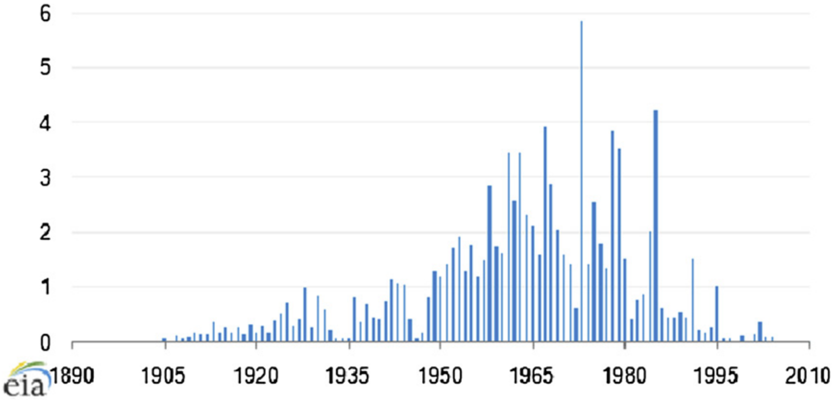

Figure 4 Current (2010) capacity (in gigawatts) of large-scale hydropower generators in the United States, by initial year of operation (http://www.eia.gov/energy_in_brief/hydropower.cfm).

now one of the oldest energy resources in the United States, however, and hydropower facilities represent approximately 70% of generating plants over 60 years old (US Energy Information Association). After dropping abruptly in the 1970s because of increasing regulations and resistance from environmental groups, most hydropower development eventually slowed to a halt by the 1990s. Hydropower capacity in the United States has not risen appreciably since.

Given the dependence on both potential energy and streamflow, hydropower is concentrated in wetter regions and regions with steep terrain. As illustrated in Figure 5, these mainly include the western and eastern mountain ranges of North America, with relatively limited production in the continental interior. The highest regional capacity occurs in the PNW (the focus of this chapter), which includes the southern portion of the Canadian province of British Columbia (BC), and Washington, Oregon, and Idaho of the United States. The steep, wet environment of the PNW enables hydropower to supply nearly all of the region's energy needs, particularly in a wet year.

Although hydropower capacity grew for most of the twentieth century, energy demand of all forms, including hydroelectricity, far outpaced this growth. Since the 1950s, electricity demand was met by thermal fuels, primarily coal-fired generation and natural gas. Natural gas capacity in particular has seen large increases in the last two decades (Figure 6), in part because it is cheaper and is considered cleaner from an emissions standpoint than coal-based generation. This trend is likely to continue owing to recent advances in hydraulic fracturing as a means to extract gas from deep-lying shale formations. Shale gas extraction is projected to grow fourfold over the next 25 years, based on an estimate of 827 trillion cubic feet of technically recoverable reserves (Annual Energy Outlook 2011, EIA). Environmental resistance to shale gas extraction methods is currently rising, however, as impacts such as groundwater contamination are beginning to be understood and

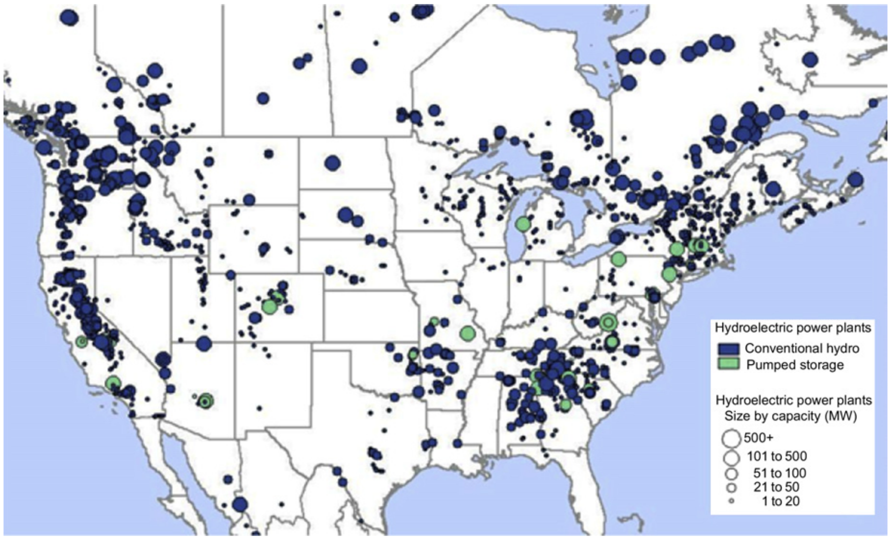

Figure 5 Hydroelectric generators in and around the United States. (U.S. Energy Information Administration, Today in Energy, June 10, 2011).

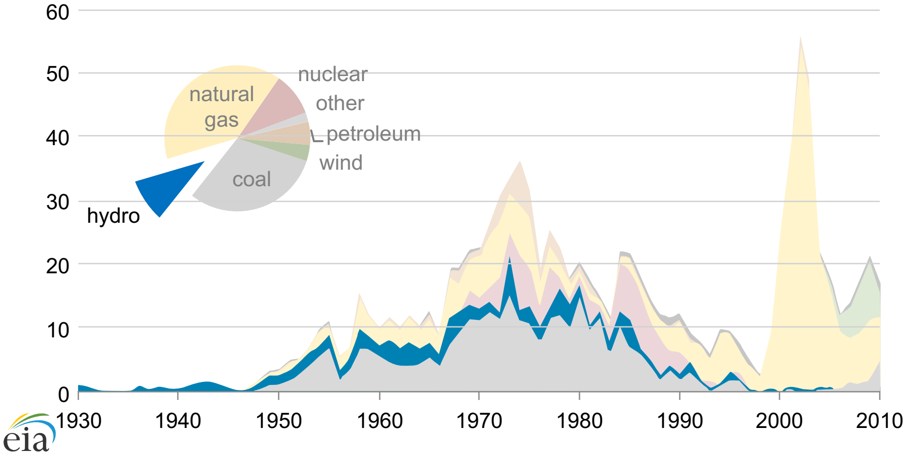

Figure 6 Current (2010) capacity by initial year of operation and fuel type (in gigawatts). Source: U.S. Energy Information Administration, Form EIA-860 Annual Electric Generator Report, and Form EIA-860M (March 2011 Electric Power Monthly).

the emissions associated with shale gas extraction and use are better quantified (current estimates range from half to double that of coal generation).

Although the diminishing marginal value of new hydropower sites was another factor in the decline of hydropower development, viable locations for new hydropower facilities do exist. The United States, for example, has an estimated potential to add 30 GW, about 40%, to current conventional hydropower capacity (US Department of Energy's Hydropower Program assessment report, as reported in US Bureau of Reclamation, 2005). The existence of significant potential for future hydropower development implies that the future of hydropower depends in no small measure on the constraining forces that have brought the virtual moratorium on new large-scale plants in the developed world. These forces are discussed in the following section.

5.12.3 Environmental and Social Consequences of Hydropower

Despite an appreciation of hydropower's benefits, the rapid growth of hydropower in the twentieth century spurred rising opposition from environmental groups. This section describes several of the key elements fueling negative societal perceptions of hydropower.

5.12.3.1 Environmental Impacts of Dams

There is little argument over the nature of many of the physical changes wrought by the construction and operation of a reservoir, as these can be quantified by measurement or modeling, or entail recognizable alterations of the watershed or landscape. Whether these represent adverse impacts, however, may be a matter for debate, reflecting the social and political values of those affected by the reservoir, and in some case of interest groups around the globe. In a modern example, concerns voiced during the construction the Three Gorges Dam in China illustrate modern antidam environmental, social, and political sentiments. That the 20 GW of hydropower capacity may replace 'dirtier' electricity sources (e.g., coal burning) or enhance rural electrification is generally viewed as beneficial, but detrimental environmental consequences include the flooding of riverine habitats; fragmentation of natural surface water systems, habitat, and fisheries; and alteration of the natural hydrologic cycle and sediment budgets. These and other types of impacts, some of which are more general, are described below.

5.12.3.1.1 Conversion of a Free-Flowing River to a Reservoir

Perhaps the most obvious consequence of hydropower development that requires damming a river is the creation of a static body of water (i.e., an artificial lake or reservoir) that inundates previously riparian and upland areas and submerges a reach of a previously flowing river. While the scale of this change to the existing natural system varies with the scale of the impoundment, the disturbance significantly alters associated aquatic habitat and adjacent terrestrial ecosystems. Depending on the size of the reservoir storage, the watershed's natural cycle of runoff (driven by temporal climatic variation and watershed characteristics) is typically disrupted. Because the reservoir water surface is larger and detained water is exposed for longer to evaporative forces than the original river surface, the outflow of the river may decrease significantly, particularly in arid areas. Evaporation from Colorado River's Lake Mead, for example, depletes the average flow volume by an estimated 8% each year (Westenburg, et al., 2006). To date, over 400 000 km^2 of the Earth has been flooded by dams.

5.12.3.1.2 Fragmentation of River Ecosystems and Impact on Fisheries

Added to the alteration of the timing of the hydrologic cycle, which can impact dependent species, large and small dams create a barrier obstructing the upstream and downstream movement of migratory river animals and anadromous fish such as salmon. Dams block fish migration upstream to spawning areas, and the relatively slack water in reservoir pools exposes fish to predation and unnatural temperature and water quality regimes, with consequent impacts on reproduction and the species population. In the Columbia River system, approximately 55% of the watershed area is no longer accessible to ocean-going salmon as a result of dams. Salmon species have vanished from many PNW streams, and other stocks have declined since the advent of the dams. Dam-related efforts to combat salmon stock loss typically include the installation of artificial 'fish ladders' and specific release operations thought to enhance fish viability (such as flushing releases during outmigration), and more extreme measures include barging or trucking of salmon to circumvent the dam. Substantial federal funding since the 1970s also supported the development of 'fish friendly' turbines that marginally increase the survival of fish passing through the powerhouse. Estimates of salmon recovery costs in the PNW range from \$6 billion to over \$10 billion during the past 30 years. While fish ladders and other measures are clearly beneficial, the overall effectiveness of salmon recovery measures remain unclear, in part because other factors such as ocean and downstream harvest of salmon and sea surface temperatures (SSTs) also affect salmon populations. Fish species such as lake trout may thrive in the reservoir environment, however, supporting recreation but representing a species shift from pre-dam conditions.

5.12.3.1.3 Alteration of Sediment Budgets and Water Quality

Rivers transport sediment down their riverbeds, allowing for the formation of riverbanks, river deltas, alluvial fans, braided rivers, oxbow lakes, levees, and coastal shores. Dams obstruct the flow of sediment downstream, leading to downstream erosion of these sediments while increasing sediment build-up in the reservoir. While the rate of sedimentation varies for each dam and each river, all reservoirs that were not designed with a flushing capability develop a reduced water-storage capacity, hence a decreased ability to produce hydroelectric power or to store water for irrigation, water supply, and flood control. The reduction in sediment supply downstream also alters shoreline and river delta ecosystems and can cause coastal erosion.

Reservoir water may be warmer in the winter and cooler in the summer than it would be otherwise, which affects the plant and animal life present in both the reservoir and, via releases, those in the river downstream, leading to losses among endemic species. In the PNW as in many regions, maintaining river temperatures and other water quality parameters (such as dissolved oxygen) within limits deemed acceptable by biologists and ecologists represents a common constraint to reservoir operations.

5.12.3.1.4 Greenhouse Gas Emissions

Although widely regarded as clean energy relative to thermal fuels, reservoirs do contribute to greenhouse gas (GHG) emissions as a result of releasing methane from anoxic sedimentary layers at the bottom. Although research in this area is still relatively sparse, some estimates suggest that for warm-climate reservoirs with large surface areas and substantial sediments, these releases can be greater than those from oil-fired generation of equivalent capacity.

5.12.3.2 Social Consequences of Hydropower Development

Hydropower brings both societal benefits and challenges. Abundant renewable energy is an obvious advantage, and stakeholders in multipurpose reservoir systems additionally depend on water supply and flood control functions. However, social losses also exist, and extend beyond the environmental concerns discussed in the previous section. Most energy-related facilities (including clean energies such as wind farms) are rarely popular in close proximity to human habitation, but many, such as gas-fired generators, have a much smaller footprint than a large hydropower facility. The largest hydropower schemes, in contrast, may require the displacement of large numbers of people and the demolition of their towns or villages. China's Three Gorges project involved the dislocation of over 1 million people, a record for dam-related construction.

In addition to long-term resettlement, the construction phase of hydropower is notorious for impacts on nearby population. Although construction may provide employment for a number of years while the project is built, and a small number of positions associated with dam operation afterward, hydropower development, as an industry saying goes, "is synonymous with delay." Hydropower development requires a complex orchestration of financing, permitting, and political support, in addition to multiple kinds of engineering effort (civil, electrical, and geotechnical) that in some cases proceed in the face of significant uncertainty. Large hydropower facilities commonly take longer than a decade to build, during which the lives of nearby inhabitants are affected.

After a project is built, nearby human populations may also be affected by increases in disease vectors such as mosquitoes carrying malaria (especially in tropical areas) that breed in the slack water created by the reservoir pool. Other deleterious ecological effects that cascade into human impacts include changes in the water inputs to lands downstream of the reservoir. Savannahs and agricultural lands that depend on periodic flooding from a seasonal runoff cycle may be altered, degrading grazing lands and fields historically cropped during flood recession, depriving farmers of their livelihood and leading ultimately to further resettlement.

The hydropower industry is cognizant of the need for social approval for new development and the potential for organized opposition to delay or block a project, with financial consequences for all parties involved. Steps to win and demonstrate local to regional support for projects are now a prominent feature of hydropower development for both small- and large-scale projects.

5.12.4 The Regulatory Environment

Environmental and social concerns about hydropower development impact hydropower growth via their incorporation into governmental regulations. The evolution of the regulatory environment, spurred in part by issues described in Section 5.12.3, has shaped the outlook for hydropower today. Regulations reflect a broader body of policy objectives relating to water resources, many of which predate the modern hydropower industry. The use of water resources in the PNW (as elsewhere) is regulated to account for environmental, economic, and social needs; to strike a balance for competing the use of water among multiple stakeholders of large reservoir systems; and to accommodate technological advances.

While federal policy regarding interstate water management in the United States dates to the constitutional landmark decision under the Commerce Clause in 1824, its implementation was initially limited to the development of navigation and its safety. By the middle of the nineteenth century, the federal responsibility included flood control (via the US Army Corps of Engineers, USACE). Early in the twentieth century, the advent of the hydroelectric industry and the need for irrigation in the western states introduced new and often competing demands for water resources, and conservation began to be an objective for policy makers.

Today, the regulations and interests of various agencies and organizations govern the hydroelectric industry. Social and environmental needs are evaluated by a number of federal and state agencies, First Nations, and state water quality and other agencies. In the United States, these include, but are not limited to, the Environmental Protection Agency (EPA), the Department of Agriculture's Forest Service, the Department of Commerce's National Marine Fisheries Service, and the Department of the Interior. Among these groups, the Federal Energy Regulatory Commission (FERC) is the major energy regulatory body in the United States, with responsibility for licensing or relicensing the project construction and operations oversight of existing projects, including dam safety inspections and environmental monitoring. FERC authority derives from the Federal Power Act (FPA) of 1920. FERC licenses have terms ranging between 30 and 50 years, a relatively long period but often shorter than a project's design life. The Electric Consumers Protection Act (ECPA) of 1986 expanded focus beyond power objectives to include mitigating environmental and social impacts in the hydroelectric licensing process, as well as enhancing energy conservation, fish and wildlife, recreational opportunities, and the preservation of other aspects of environmental quality. Despite several reforms (e.g., in 2003, FERC approved the current 'default' licensing process – the *integrated licensing process*) to streamline the licensing process, the time required to obtain a hydroelectric license has grown from 2 to 4 years, and the licensing cost has doubled, making hydroelectric facilities less competitive with other conventional power-generating technologies. By comparison, natural gas generation is faster to permit and build, and consequently carries less developmental risk and potentially lower costs.

In British Columbia (BC), Canada, government legislation restricts the development of large hydro facilities at particular sites, although most existing BC Hydro projects have water/use licenses that have been issued for perpetuity. Like any other type of generation, hydropower needs to comply with the environmental regulations, including the BC Environmental Assessment Act (for plants with installed capacity greater than 50 MW) and the Canadian Fisheries Act (for hydro developments impacting fish). The BC policy framework derives from the BC Power Authority (BC Hydro) and long-term acquisition, and integrated resources plans are regulated by the BC Utilities Commission. In general, the government energy policy goal is to reduce GHG emissions; increase the demand side management; encourage utilities to produce, generate, and acquire electricity from clean or renewable sources; encourage utilities to develop adequate energy transmission infrastructure and capacity; and encourage utilities to use innovative energy technologies that facilitate electricity self-sufficiency and meet environmental requirements. Consequently, hydro generation, both large scale and run of river, is a part of the integrated resource plan in BC.

Although the regulatory environment is more permissive in BC than in the United States, the hydroelectric industry has shifted from development of large dams to improving operation and increasing the efficiency of existing assets and small upgrades at existing plants. In addition, some development of small dams with run-of-river power plants has occurred, albeit without significantly increased total hydro generation capacity. Where new project development in North America does occur, it illustrates the modern realities of regulatory compliance. Near the PNW, one example is the proposed 1100-MW Site C power station in northern BC, Canada, to be built by BC Hydro with planned completion in 2021. The project will undergo an independent environmental assessment (EA) process that includes multiple opportunities for consultation and input by the general public, Aboriginal groups, communities, property owners, and stakeholders. Like any proponent of a large project with potentially significant impacts, BC Hydro will identify and assess possible project effects – environmental, economic, social, heritage, and health – and opportunities to provide lasting benefits for the region and Aboriginal groups. Where deleterious effects cannot be avoided, BC Hydro must identify and propose options for mitigation. Even given sufficient hydrologic resources to support an economically productive project, failure to convince stakeholders may result, at a minimum, in project delays and cost increases, and ultimately, the outcome of the EA process could be either approval or rejection of the proposed project.

5.12.5 Hydropower in the Context of Renewable Energy

Hydropower, wind, solar, biomass, geothermal, and other forms of renewable energy have existed for decades, but growth in non-hydropower renewable energy has rapidly accelerated in recent years. The sector's growth is motivated by social, political, and economic interests such as energy security and by concern over anthropogenic climatic change, and is supported by advances in renewable technologies. Hydropower still accounts for over half the modern renewable energy resources (Figure 7), which supply roughly 20% of the world's electricity (see Section 5.12.2 Harnessing Hydropower: An Overview), but hydropower in developed nations has not shared in the recent boom.

In the United States and other nations, renewable energy growth has been promoted via deliberate policymaking to spur a switch from thermal energy sources. Many US states have incentivized renewable energy development using Renewable Portfolio Standards (RPS) regulations, which require utilities to generate a certain fraction of energy from renewable energy sources, such as wind, solar, biomass, geothermal, and, to a degree, small hydro. No RPS exist yet at the federal level, and state-level RPS vary from nonexistent to aggressive (e.g., California's 33% by 2030). Renewable power is also incentivized by Production Tax Credits (PTC) that are proportional to the power generated and by other legislated measures. For solar power, incentives come in the form of feed in tariffs, which compensate generation that is supplied to the regional grid. In contrast to the other technologies, however, hydropower has been excluded or de-emphasized in many US renewable incentives. The rationale is not hard to fathom. In Washington State, for example, the RPS objective is for 15% of energy use to come from renewable sources by 2020 (http://apps1.eere.energy.gov/states/maps/renewable_portfolio_states.cfm) – yet hydropower already represents 75% of the current electricity resource; thus including existing hydropower would obviate the RPS initiative. The hydropower industry has fought for recognition of some aspects of hydropower as renewable, winning some concessions (e.g., for plants within the small hydropower category, for turbine capacity upgrades to larger plants, and for small-scale hydrokinetic technologies), but without achieving parity with other renewables. Regulatory and market incentives for small, run-of-river hydro exist with certain constraints, but are not in place for the development of new large-scale hydropower generation.

The renewable supply side resources that can provide utility-scale energy (e.g., sufficient to power at least a small town) at a reasonable cost are wind, hydro, ocean (tidal and wave), solar, geothermal, and biomass. Since the only incentivized forms of hydropower are primarily small hydro facilities or hydrokinetics, the remaining clean energy options are biomass and geothermal resources, which have their own drawbacks (scale, fuel availability), and wind and solar power, which are intermittent – that is, subject to large variations on timescales of minutes to days.

Power systems are extremely complex. The mechanisms responsible for their control and transmission enforce system stability by continuously adjusting the supply of electric energy to match the instantaneous, aggregate fluctuating electric demand of customers (i.e., the load). Stable operation of the system thus requires the ability to raise or lower the output of generating units to respond to fast fluctuations in load, as well as a 'spinning reserve' of power that can be brought on line (dispatched) relatively quickly to meet the load in case of unplanned loss of significant generating unit or a major transmission line. The activities and functions necessary for maintaining system performance and reliability are called *ancillary services*.

Intermittent resources do not have energy storage. Generation is driven by physical phenomena – essentially, the weather – thus the prediction and commitment of intermittent renewable power for any future period (even an hour ahead) carries uncertainty, with forecast accuracy typically diminishing with forecast lead time. Despite small, non-utility scale advances in battery technology, intermittency particularly characterizes wind and most solar power, and less so small run-of-river hydropower. The combination of renewable power variability, lack of storage, and relatively high uncertainty of generation forecast makes it challenging to integrate wind (and other intermittent renewable) generation into established practices for long-term energy planning, in addition to system operations.

While the intermittent resources do provide, in the time-averaged sense, reliable energy supply, their ability to provide capacity – *dependable capacity at high reliability* – is limited unless reserves are also available. Yet systems need both energy and capacity: in long-term planning of electric power systems, overall reliability is often measured in terms of the probability that the planned generation capacity will meet the future peak load. The installed capacity of intermittent resources may exceed a projected load, but there is no guarantee that the capacity will be available at the time of the demand. For example, wind farms in the PNW generate more energy at night than during the peak energy demand hours during the day.

At large conventional hydropower plants and smaller pumped storage facilities, the existence of a reservoir (energy storage) or reverse pumping capacity provides much needed flexibility to buffer variability in intermittent generation. Storing water (energy) when it is not needed and generating when energy is needed is economically attractive (the price of electricity drops when the demand is low and rises at the times of high demand). Hydropower plants also have a very fast response time (they can turn on and off generation quickly),

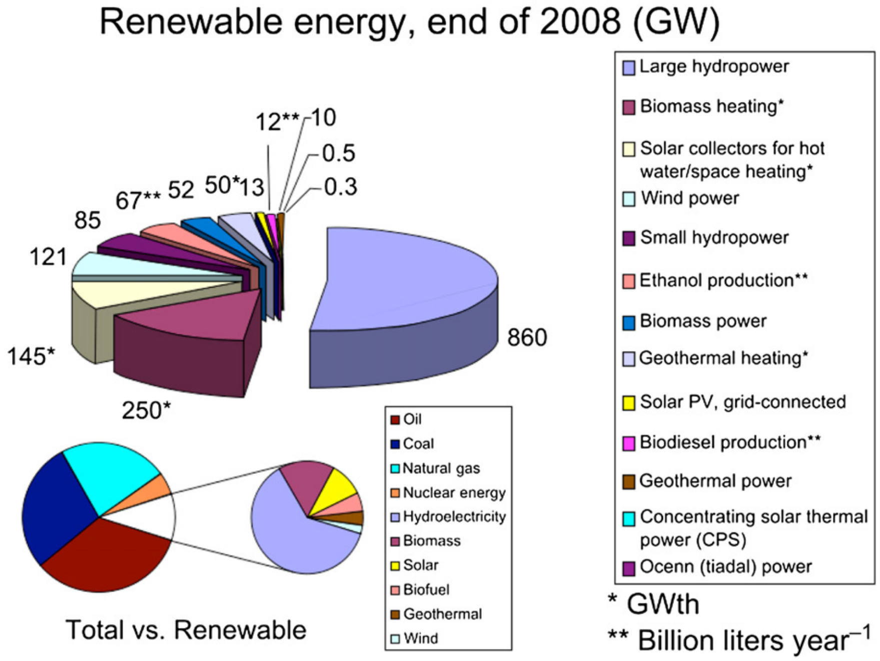

Figure 7 Global renewable energy (in GW) in 2008. Source: http://en.wikipedia.org/wiki/File:Ren2008.svg.

which makes them a prime choice for energy reserves. Gas-fired power plants, another suitable choice for energy reserves, can be subject to supply disruptions or price fluctuations. Their response time is not as quick as that of hydropower plants and they are a less attractive solution from the standpoint of GHG emissions. Nonetheless, an unappreciated consequence of rapid wind farm growth in areas without sufficient hydropower is a requisite expansion of gas-fired generation. In Europe, the penetration of wind and solar power into energy markets has depended on access to hydropower (e.g., in countries such as Norway or in pumped storage facilities) as a means of grid integration. Even in areas with currently sufficient hydropower, the existing hydro systems have a physical limit on providing reserves for the integration intermittent resources. In the Pacific Northwest, for instance, the hydropower system is nearing an integration limit, given current multiobjective operation constraints, as 6000 MW of wind energy comes on line. New flexible resources to compensate for intermittent energy supply will be needed in the future.

Large hydropower reservoirs provide the most flexible and potentially economical energy storage today, and this role is relatively new in an industry that does not change quickly. Owing to regulatory constraints (see Section 5.12.4), large hydropower is currently a more expensive option for renewables integration than gas-fired plants. Run-of-river reservoirs can also serve as storage, but their contribution is more limited and costlier than that of large hydropower. Pumped storage hydro can provide integration services and can be economical if the spread between the peak-hour electricity prices and nonpeak-hour electricity prices is high. The licensing and construction of new pumped storage facilities remains very difficult, however, and only 34 plants exist in the United States.

It is clear that hydropower could play a critical role in a transition toward the renewable energy future that is envisioned in current market incentives and renewable energy policy. The water and power management agencies, regulators, and the hydropower industry are now grappling with the complexities of defining that role, given social and environmental constraints established decades ago, as the footprint of intermittent renewables continue to grow.

5.12.6 Hydropower in the Face of Nonstationarity

Changing societal values and awareness of environmental impacts have significantly shaped the evolution of hydropower, yet hydrologic and climate research increasingly raises other concerns that may alter the outlook for hydropower. Since the later decades of the twentieth century, global change research has brought increasing attention to the concept of nonstationarity in hydroclimatological and land surface elements of the Earth system. This chapter adopts the concept of nonstationarity from an engineering context: that the practice of using statistical descriptions of system behavior based on the relatively short record lengths (often 30–50 years) for long-term planning is invalid if system properties vary on longer timescales than were measured by the observed record. This focus on non-stationarity has been highlighted in part by international groups such as the Intergovernmental Panel on Climate Change (IPCC), which placed a primary emphasis on changes in climate while also describing causative, consequential, or interrelated changes in other physical variables. Like other sectors having operational dynamics that are influenced directly or indirectly by changes in geophysical processes, hydropower is sensitive to nonstationarity. This section provides perspective on the major sources of geophysical nonstationarity that affect hydropower: low-frequency hydroclimatic variability, climatic change, and large-scale land surface change or disturbance.

5.12.6.1 Terrestrial Hydrologic Variability: Land-Use and Landscape Change

Processes occurring at the land surface, in some cases partially related to climatic variability and in other cases not at all, can also induce strong long-term changes in river discharge and dynamics. Land-use and land-cover (LULC) change is a particularly clear example. It has long been known, for instance, that urbanization – the replacement of permeable land covers (forests, wetlands, agricultural crops, etc.) with impermeable surfaces (rooftops, paved road surfaces, etc.) – generally leads to a particular set of related hydrologic responses, including flashier streamflows, higher peak flows with increased erosion and flooding potential, and lower baseflows with potential implications to aquatic habitat availability.

In the PNW, forestry practices represent another source of large-scale systemic change. In general, forest harvest in a catchment has been shown to yield greater overall water supply, faster snowmelt, and higher peak flows. These hydrologic changes result from the removal of vegetation (which reduces sublimation and evapotranspiration), soil compaction (which reduces infiltration), increased insolation due to canopy loss, and road building (which channelizes runoff, speeding overland flow), among other physical changes. There are exceptions to these effects, and they damp out after a number of years as understory and then overstory recover. Recovery times (in terms of hydrology) to such disturbances can range from a decade to generations, depending on local circumstances. A detailed review of these impacts is provided by Moore and Wondzell (2005).

Another important LULC process is large-scale deforestation and associated hydrologic impacts of species of insects such as the mountain pine beetle (MPB), which infest and cause mortality in trees. The MPB is a pest species native to northwestern North America that has devastated large tracts of forest in the last few decades. Current infestations are believed to be much larger than previous outbreaks, possibly reflecting a combination of past forest management practices and climatic changes. The increase in MPB infestations has also been linked to regional warming, and in particular the elevation of nighttime temperatures that, in colder decades, were low enough to kill beetle larvae. The hydrologic impacts are similar in nature to those often associated with forest harvesting (see above), but forest ecosystem changes associated with beetle kill are a multiyear phenomenon and involve more gradual and complex interplay of disturbances to the initial ecosystem. Current research on the near-term (1–10 year) hydrologic impacts in western North America is inconclusive; nonetheless, where the land cover may change from forest canopy to a sparse vegetation cover, harvest-related research suggests that greater watershed yields will result, together with earlier freshet timing in snowmelt areas. Beetle kill impacts may also be exacerbated by salvage logging operations. For a useful review, see Redding et al. (2008).

Glacier changes also have the potential to cause long-term hydrologic changes in the PNW. Overall, glaciers can be an important control on hydrograph form – increasing the water yield of a basin and providing increased flows in late summer when rain- or snowmelt-driven basins in the region are largely depleted of runoff generation sources. Today's mountain glaciers in the PNW represent the remnants of the last Pleistocene ice age. On this very long-term retreating trend are superimposed decadal- to centennial-scale increases and decreases in ice volume, and associated termini advance and retreat, generally associated with climatic fluctuations. Historically, the pattern in western North America has largely been a negative mass balance and glacial retreat under a warming climate. These changes have had significant effects on runoff in the PNW. However, while the glacier state is strongly connected to climate, internal glacier dynamics are also significant and complex, perhaps especially in larger ice masses such as the major ice fields that still cover portions of Canadian headwater basins to the Columbia River and parts of the BC Coast Range. One consequence is that even if historical warming trends were to cease today, glacier recession and the associated hydrologic changes would likely continue for decades. An extensive review of historical and potential future impacts of glacier change in western North America is provided by Moore et al. (2009).

Many, if not most, studies on urbanization, forest harvesting, MPB, and glacier change impacts on stream hydrology have focused on small basins. The manner in which these impacts integrate to larger spatial scales is less clear. Nevertheless, our current understanding of such processes leaves little doubt that they may impact certain types of hydroelectric generation, for example, new microhydro plants in glacier-fed watersheds in BC coastal mountain areas.

To the extent that some LULC processes are associated with climatic variability or change (such as MPB or glacier change), their effects may be regarded as pathways through which climate impacts hydrology, with an associated potential to alter hydropower prospects for better or for worse. The LULC changes may also affect local land–atmosphere feedbacks, such as alterations in the roughness driving turbulent fluxes in boundary layer meteorology, cascading into patterns of precipitation deposition, wind (hence evaporative demand), soil moisture, near-surface air temperature, and other phenomena that in turn further influence land surface hydrology and runoff. Such impacts may best be understood by incorporating these processes into comprehensive modeling approaches, although the complexity of the coupled earth system and sparsity of data for validation complicates the verification of model sensitivity results. In all, streamflow impacts resulting from LULC that determine; may influence the timing and quality of runoff more than the seasonal or annual inflow quantities on which hydropower capacity depends.

5.12.6.2 Hydroclimatic Variability and Trends

The atmosphere and ocean exhibit complex forms of variations over a wide range of time and space scales, ranging from second-to-second wind gusts at a particular headland to millennial- or even longer-scale oscillations or trends in global climate, with cascading effects at regional and local scales. Although more than a dozen modes or patterns of this variability have been proposed and/or identified, two in particular have been widely studied for their influence on climate and streamflow in the PNW: El Niño–Southern Oscillation (ENSO), which exhibits a cycle of a few years in length, and the Pacific Decadal Oscillation (PDO; Mantua et al. 1997), which, as the name implies, spans a few decades. Most hydropower infrastructure and operations are designed to manage variability on the interannual timescales associated with ENSO (i.e., buffering variation between dry and wet years). In contrast, 'low-frequency' decadal variability or longer persistence-related processes that appear as trends in conventional observational records present a challenge that is only implicitly addressed by storage and management. In addition, the vast body of research on climatic change suggests the possibility that observed long-term variations may now include a trend component resulting from anthropogenic GHG forcings of the climate system. The following subsections describe important features of these coherent modes of climatic variability, with emphasis on low-frequency modes and also summarize hydroclimatic findings related to climatic change. Note that interannual and 'low-frequency' variability are here separated because of their different impacts on water systems, but the definition of frequencies that are 'low' is context dependent. Interannual variability can also be considered 'low frequency.'

5.12.6.2.1 El Niño–Southern Oscillation

Although ENSO is a continuous process, three distinct ENSO states are customarily defined: El Niño (warm phase), neutral, and La Niña (cool phase). To first order, ENSO involves a 'sloshing' of warm surface water back and forth across the equatorial Pacific Ocean. During El Niño events, the easterly (i.e., west-directed) trade winds slacken or even reverse. Warm surface waters normally pooled in the eastern Pacific consequently flood westward into the central and eastern Pacific. Roughly the opposite happens during La Niña events, with strengthened trade winds and reinforcement of the usual upwelling of cool water in the eastern Pacific. Pacific SST anomalies during a recent La Niña are plotted in Figure 8.

The temporal signatures of ENSO are variable, but some consistent patterns exist. Individual El Niño and La Niña events typically last for 6–9 months but can in some cases remain in one phase for up to several years, and ENSO is generally described as being quasi-periodic and operating on timescales of about 2–6 years. Over most of the PNW, La Niña gives cooler winter and spring temperatures, on average. It also tends to yield higher winter precipitation, but this signal is less consistent, both year-to-year and between locations. El Niño effects are only roughly the opposite. Most importantly from a water resources perspective, any given ENSO event may exhibit local impacts that deviate – sometimes substantially – from the average for that type of event. Useful map summaries of typical ENSO impacts on Canadian and US surface temperature and precipitation are available through, respectively, Environment Canada (www.ec.gc.ca/adsc-cmda/default.asp?lang=En&n=45475BB4-1) and NOAA (www.cpc.ncep.noaa.gov/products/precip/CWlink/ENSO/composites/EC_LNT_index.shtml).

The overall effects on river flows in the region have been progressively refined in a substantial number of studies over the past 20 years (e.g., Redmond and Koch 1991; Woo and Thorne 2003; Fleming et al. 2007; Gobena et al. 2010) and are consistent with climate effects – i.e., toward higher flows in La Niña years and lower flows in El Niño years. The flow timing impacts of ENSO can vary from river to river, however. In predominantly snowmelt-fed rivers that are typical in many mountain and inland portions of the PNW, winter precipitation falls mainly as snow to be stored until the spring freshet, and the runoff impacts of La Niña show a commensurate delay. In predominantly rainfall-driven rivers, common in low-elevation coastal areas, the impacts are instead felt contemporaneously with the occurrence of the wintertime driving climate anomaly.

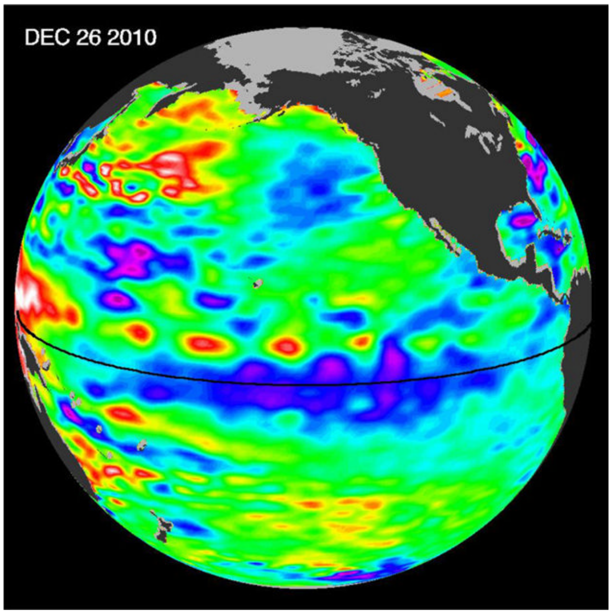

Figure 8 The 2010–11 La Niña event appears as a band of cool water (marked in blue hues) along the equator in this view of the Pacific Ocean from space. Courtesy of NASA/JPL-Caltech.

In medium- to high-elevation rivers, where snowmelt contributes substantially to flow, the temperature impact of La Niña can additionally be important. Many PNW rivers have both a winter rain freshet and a spring snowmelt freshet. Cooler temperatures can cause a greater proportion of the winter precipitation to fall as snow rather than rain, potentially shifting runoff from winter to spring. For such mixed-regime rivers, as well as inland and high-elevation basins dominated by snowmelt, cool winter–spring temperatures also shift the freshet timing – with cold-phase years, for example, typically showing delayed freshets. Again, the effects of El Niño are generally but not exactly opposite. Because ENSO imparts a clearer and more consistent signal to temperature than to precipitation, the corresponding river flow effects (i.e., on flow timing) are in general more reliable.

ENSO is the leading mode of interannual-frequency planetary climatic variability (Wallace and Thompson 2002; Hoerling et al. 1997). Owing to the predictability of ENSO effects on climate and flow, operational ENSO-based forecasting is conducted at a number of institutions using a variety of deterministic and statistical models. Summaries of current conditions and forecast compilations and interpretations are presented, for example, by NOAA's Climate Prediction Center (www.cpc.ncep.noaa.gov/products/analysis_monitoring/enso_advisory/) and Columbia University's IRI (iri.columbia.edu/climate/ENSO/

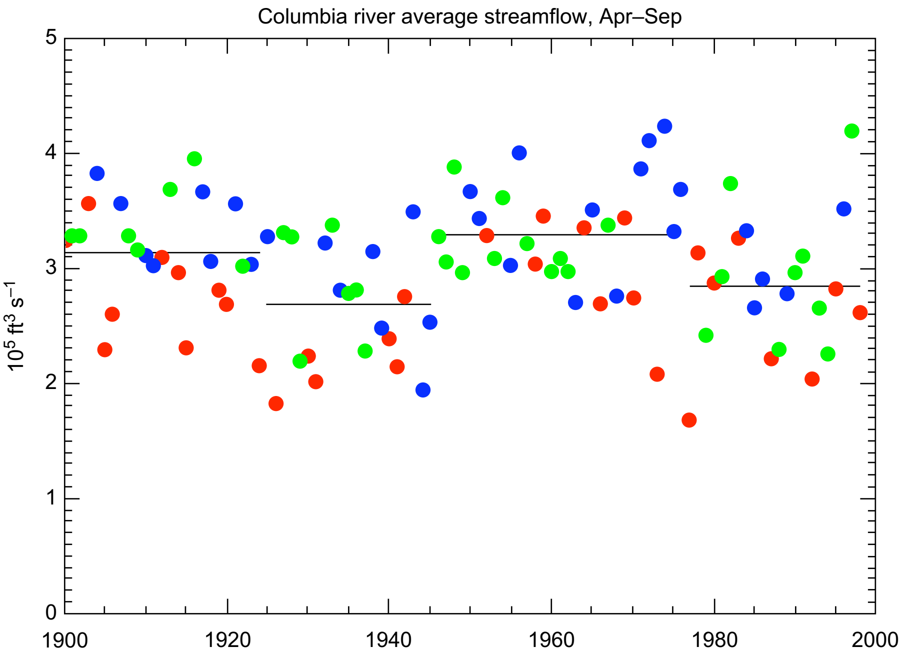

Figure 9 The influence of ENSO and PDO on Columbia River naturalized summer streamflow at The Dalles, Oregon. The horizontal lines show average streamflow over PDO epochs (cool: 1900–25, warm: 1925–45, cool: 1945–77, warm: 1977–95). currentinfo/SST_table.html). ENSO-attributed climatic variations can produce large variations in PNW hydropower; thus, forecasting is an important input for management in a wide range of climate and water-related sectors and represents an active source of advances in hydropower management efficiency.

5.12.6.2.2 Pacific Decadal Oscillation

The second major form of coherent climatic variability affecting the water resources and hydropower of the PNW is the PDO. The PDO is manifested as an east–west dipole in North Pacific SST. Whitfield et al. (2010) provides a recent and thorough review of the PDO and its impacts on water resources in western Canada; some of the major salient points are briefly discussed below.

Like ENSO, the PDO arises from oscillatory dynamics within the Pacific Basin, involves an east–west movement of Pacific surface water temperature anomalies, and has similar signatures in the surface meteorology and hydrology of the PNW. Figure 9 shows that warm ENSOs and PDOs tend to decrease streamflow and cold events tend to increase streamflow, and also illustrates their different temporal variability. ENSO consists of cold- and warm-phase episodes of at most a couple of years in duration that are generally punctuated by neutral years, whereas the PDO has been characterized as abruptly shifting between warm and cold regimes, each lasting for decades, typically without a neutral, intervening state. ENSO also differs in that it is defined by tropical Pacific variability, whereas the PDO is widely regarded as a North Pacific phenomenon. In contrast to perspectives on ENSO, the scientific community's knowledge about the fundamental origins of the PDO is limited. The PDO cannot be predicted with current methods, and current general circulation (e.g., climate) models (GCMs) struggle to reproduce the phenomenon. In fact, because the PDO remains defined solely on the basis of empirical data analysis and year-to-year climate is noisy, PDO regime shifts cannot be identified until they are several years in the past. Furthermore, researchers disagree over whether PDO regime shifts reflect true oscillatory behavior or are instead a misinterpretation of a stochastic red-noise process, mainly because the long characteristic timescale of the PDO – perhaps 30–50 years – means that most nonpaleo records are insufficient to distinguish between the fundamentally different models of PDO (Overland et al. 2006; Fleming 2009a).

Despite caveats and limitations, the PDO remains a highly valuable framework for understanding decadal-scale variability in the climate and water resources of the PNW. On average, warmer and drier conditions occur through much of the PNW during the PDO warm phase, giving earlier freshets, partial shifts of runoff timing from spring freshets to winter freshets in hybrid coastal hydrologic regimes, and lower overall water supply availability. The PDO cool phase is associated with loosely opposite conditions. Note that many of the complications identified above with respect to ENSO also apply to the PDO, including nonlinear teleconnections, sensitivity of hydrologic response to local hydrologic regime types, and the substantial within-epoch variability (i.e., not all years during a warm PDO regime will have warm PDO characteristics). Nonetheless, the PDO phase serves well as a general index of prevailing PNW climate and streamflow conditions.

5.12.6.2.3 Nonlinear Dynamics: Long-Memory Effects

On longer than decadal timescales, geophysical system memory is also relevant to outlooks for climate and hydrology.

The traditional notion of hydrologic 'memory' refers to the simple fact that river flows and other hydrologic variables change in a continuous fashion. For example, with a few exceptions, a relatively high flow right now is fairly likely to be followed by a relatively high flow a few hours or even days from now. Streamflow persistence effects arise from the regulation of hydrologic fluxes by watershed storages such as groundwater, snowpack, aquifers, and lakes, and may also incorporate persistence in driving weather or climate patterns. In statistical hydrology, the effect is often conceptualized as serial dependence and represented using linear low-order autoregressive models. However, such memory phenomena have also been observed on multidecade to near-century timescales in both hydrology and other disciplines within the physical, biological, and social sciences. The long-memory phenomena have been assessed using spectral analysis techniques and are variously termed long-term persistence (LTP), fractal dynamics, fractal noise, fractional Gaussian noise, fractional Brownian motion, $1/f$ (also $1/f^a$ or $1/f$-like) scaling, flicker noise, and the Hurst phenomenon, named for the findings of Harold Hurst regarding the temporal variability exhibited in the river stage records of the Nile River (Hurst 1951, 1957), which were over 600 years old. The physical processes driving such empirical effects are not well understood, but clearly stem at least in part from hydrologic 'resistances' or storages as well as similar effects in the climate system. Some seminal or otherwise useful examples of work in the field as relevant to hydrologic variability at a range of timescales include Hurst (1951, 1957), Mandelbrot and Wallis (1968, 1969a,b), Klemeš (1974), Booy and Morgan (1985), Livina et al. (2003), Cohn and Lins (2005), Koutsoyiannis (2006), and Khaliq et al. (2009).

The practical implication for hydropower of fractal dynamics in climate and watershed systems is similar to that of low-frequency (decadal or longer) variability. Both raise the specter of realizing extended periods of climate and streamflow that are not anticipated in facility design. That is, the observed streamflow and/or climate statistics on which water resources management system designs are typically based may fail to describe accurately the streamflow and climate regimes in which the projects will operate, causing capacity risk. If one is attempting to identify the available water supply to a proposed new hydro plant on the basis of a finite-length historical streamflow record spanning only one PDO regime, that record may contain a systematic high or low bias because the record is insufficient to identify low-frequency cycles with accuracy. Extreme events may be more frequent than inferred using standard statistical methods for flood frequency analysis. Long memory can lead to greater clustering of values (e.g., a more closely spaced sequence of flood years or longer droughts) than might otherwise be expected. It can also create apparent trends that complicate efforts to identify anthropogenic global climate change (AGCC) effects in long-term historical data records, even using statistically rigorous methods.

Paleoclimatic analysis can help to construct a more complete understanding of the hydroclimatic ranges to which water management systems may be exposed. As alluded to earlier, the major Colorado River storages (Lakes Powell and Mead) are large enough to maintain high pool levels during a few dry years, but the extended dry period of the 2000s lowered reservoir pools and streamflows to the extent that power generation dropped by 25–30% for multiple years. The paleo record contains droughts that far exceed the severity of twentieth-century droughts. Most large hydropower systems in the United States and Canada were designed before a widespread appreciation of low-frequency hydroclimatic variability; thus, the extended dry phases of such cycles represent a future capacity risk for many of these systems.

5.12.6.2.4 Climate Change Risk and Associated Hydrologic Uncertainty

Although natural but poorly understood long-memory processes may give rise to apparent trends in short observational records, another possible source of such trends exists. Population and associated economic growth have led to both extensive deforestation worldwide and widespread and intensive use of fossil fuels. The former constitutes reduction in a carbon sink, and the latter amounts to increase in a carbon source. The net effect is to substantially increase the total amount of carbon dioxide and other GHG in the atmosphere. Their transparency to shortwave radiation and opacity to longwave radiation causes a natural 'greenhouse effect' that is essential to life on Earth: the average planetary temperature would be well below the freezing temperature of water without it. In balance, the greenhouse effect supports the Earth's flora and fauna. Multiple lines of observational evidence have converged in recent decades to suggest that increases in GHG from anthropogenic sources since the Industrial Revolution have altered this balance, adding a new forcing to the natural climatic changes that have taken place throughout Earth's history (such as those associated with orbital and solar output variations, as well as geologic processes such as continental drift, mountain building, and erosion, which affect ocean and atmosphere circulation patterns). Anthropogenic climatic changes appear to be much more rapid than changes due to natural variability, possibly presenting greater adaptation challenges to both ecosystems and societies. This section will briefly review how associated hydrologic impacts are assessed, and how they may potentially be manifest in the PNW.

5.12.6.2.5 Methods of Study

Inference about potential anthropogenically forced changes in the hydroclimate follows two primary pathways. The first is to assess geophysical observations describing a broad range of earth system variables, using datasets that include both direct measurements (e.g., ground station air temperature) and proxy records (e.g., from ice cores, lake sediments). The IPCC states that estimated increases in globally averaged temperatures observed since the mid-twentieth century are very likely to be due to anthropogenic GHG increases. The scientific understanding of the effects of this warming on regional hydroclimatic parameters is incomplete, but many researchers have noted the consistency of observed regional warming and hydrologic effects with the concept of a forced climatic change impact that appears to be underway already (e.g., USGCRP 2009; Barnett et al. 2008). As an example, statistical analyses of historical streamflow data in northwestern North America by Fleming and Clarke (2003) and Stahl and Moore (2006) showed how glaciers can affect the long-term responses of rivers to historical climatic changes, and that these phenomena vary by region. Numerous analyses of the twentieth-century hydroclimate in the western United States (described in USGCRP 2009 and in the IPCC reports) have documented changes in glacial extent, seasonal snowpack, and river flows that are consistent with regional warming.

Since the mid-1990s, a second approach for estimating potential anthropogenic climatic change influences on future climate, hydrology, and water resources has involved a sequence of computational models, with the results of one model feeding into the next. The model chain begins with GHG emission scenarios that reflect different assumptions about future global socioeconomic and technological development that will affect emissions. The resulting sets of potential future GHG sequences become inputs (forcings) to GCMs (GCM is now widely used to stand for Global Climate Model, a type of mathematical–computational simulation of the land, ocean, polar ice, and atmospheric components of the global climate system that is normally run on supercomputers by various different climate science groups around the world). The relatively coarse scale output from GCMs (e.g., a 10 000 km^2 grid cell is typical) must be *downscaled* to be useful for watershed studies via either statistical or dynamical methods – the latter uses finer resolution atmospheric model simulations to transfer GCM signals. The downscaled GCM results are then used to drive process-oriented hydrologic models (e.g., Singh and Woolhiser 2002; Beckers et al. 2009; Fleming 2009b), which in turn produce streamflow scenarios that are used in water resources analysis for potential future climates.

The propagation of model uncertainties and errors through such a modeling chain leads to significant uncertainty and potential for misinterpretation in projections of future streamflows and water resources performance. A common means of quantifying the uncertainty is to employ model ensembles (i.e., a large set of GCM simulations of future climates), although most studies to date have not extended the ensemble aspect to downscaling methods or land surface modeling. The resulting distributions of projected hydrographs aim to bracket future hydrologic response uncertainty, while recognizing that this description of uncertainty is nonetheless incomplete. Analysis of climate model-based uncertainty alone (Harding et al. 2012; Deser et al. 2012) suggests that future climate uncertainty has not been captured effectively by the model-based approaches to date.

The combination of statistical analysis of historical data records for climatic trends and hydroclimate sensitivities with model-based hydroclimatic projections (which are in effect sensitivity analyses) provides important context and guidance toward potential future climatic change resource vulnerabilities. Recent hydrological variability and possible trends characterize the sensitivities of watershed systems to warming and variability in precipitation, while projections provide further 'what if?' scenarios with which a wider range of sensitivities can be explored. The following discussion describes findings from this body of analysis.

5.12.6.2.6 Projections for PNW Hydrology and Hydropower

Model-based work on the potential impacts of AGCC on water resources within the PNW as directly relevant to hydroelectric generation has included Whitfield et al. (2002), Stahl et al. (2008), Moore et al. (2011), and Schnorbus et al. (2011) in Canada; in the United States, early work describing Columbia River hydropower impacts included Payne et al. (2004). More recently, federal management agencies have released findings from similar types of studies (such as Reclamation 2011). This work assesses projections of warmer conditions for the future in the PNW and the likely streamflow impacts of such potential changes.

For PNW rivers having a substantial snowmelt component, that is, most rivers in the region except relatively small low-elevation coastal streams, the spring freshet is expected to move forward in time because of warmer temperatures. This shift would likely involve both an earlier onset of the snowmelt freshet and an earlier end. The latter might also contribute to a decrease, on average, in late-summer baseflows. In principle, greater evapotranspiration losses might also occur in late summer in a warmed climate, but the strength of this effect remains unclear. Lower baseflows in glaciated catchments, such as some Columbia River headwater watersheds (contributing energy to the massive hydroelectric complexes along the Columbia River) and various locations along the BC coast (contributing energy to a host of current, planned, or proposed small hydro and/or run-of-river projects), may also be expected as a result of ongoing glacier recession and progressive loss of melt-contributing permanent ice mass.

Warmer temperatures may also contribute to a greater proportion of precipitation falling as rain rather than snow, leading to additional timing effects. For temperate coastal basins exhibiting both winter rainfall and spring snowmelt freshets, such a transition between precipitation types would likely yield a *de facto* transfer of water from the spring freshet to the winter freshet. For colder basins located inland or at higher elevations, where temperatures would be likely to remain well below freezing through most or all of the winter even in a significantly warmed climate, the hydrologic impact of that same transition might be toward higher shoulder-season (late fall–early winter and late winter–early spring) runoff events.

From historical observations, the sensitivity of PNW streamflows to variations in precipitation is relatively clear (e.g., amplified rainfall yields higher streamflow subject to moderation by snowpack dynamics). Climate model projections for precipitation, however, are far less informative than for temperature about the direction of potential future changes. In general, studies suggest (for the PNW) a wetter climate in the mean, an increase in winter precipitation, and a decrease in summer precipitation. Confidence cannot currently be assigned to such regional projections, and indeed, different GCM projections for the PNW vary significantly from substantially drier to substantially wetter potential futures. Furthermore, the decadal phasing of precipitation changes in climate models is largely driven by unforced, thus largely random, internal model-specific variability. This temporal uncertainty, coupled with the general inability of many GCMs to reproduce comprehensively the important features of regional climates, precludes the quantification and even directional indication of precipitation-driven changes in hydrology at a regional level.

Notwithstanding these uncertainties, Figure 10 illustrates possible consequences of warming and precipitation changes for streamflow hydrographs in the PNW. Warming is manifested in the timing shift of runoff toward earlier in the year, and precipitation uncertainty is manifested in the spread of the

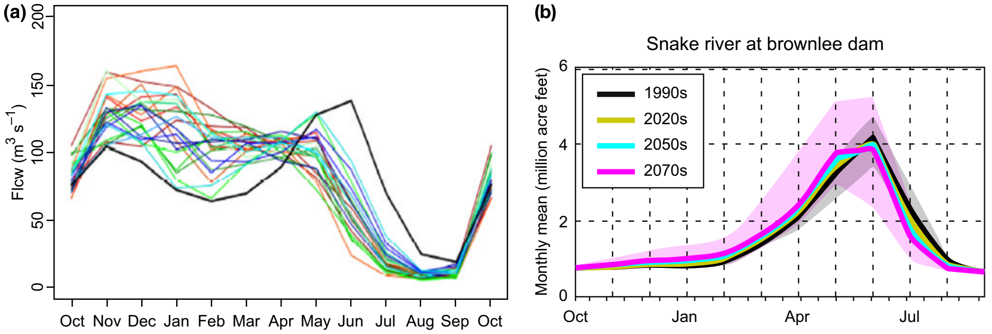

Figure 10 Projected future climatic effects on the Pacific Northwest streamflow. (a) Ensemble of median annual Campbell River hydrographs *c.*2050 (colored lines) and historical value (thick black line) (based on Schnorbus et al. 2011). (b) Simulated future mean-monthly runoff for a tributary to the Columbia River Federal Power System. Bureau of Reclamation, US Department of the Interior.

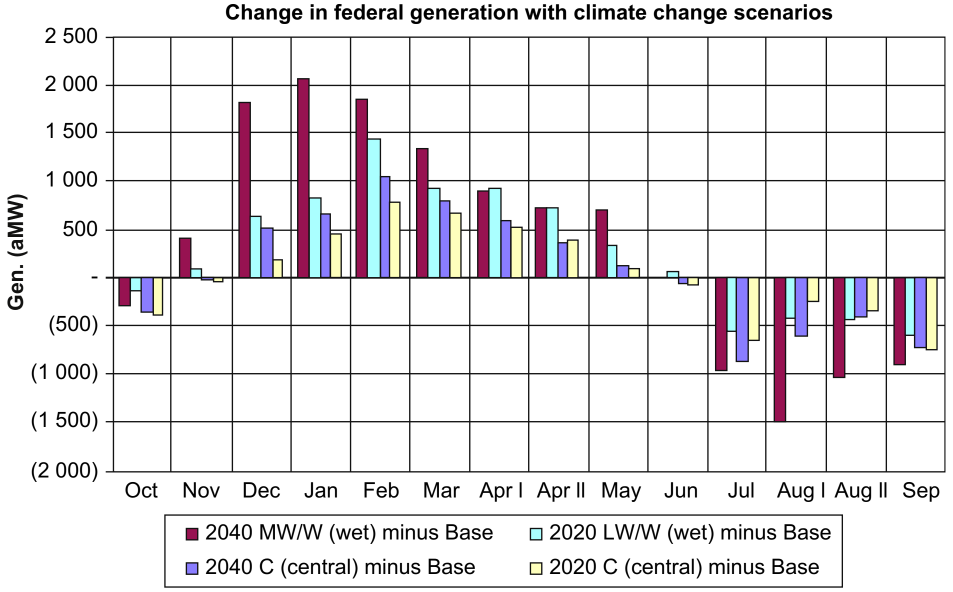

Figure 11 Impacts of projected future climate on hydropower generation in the Columbia River System. Three future climate scenarios – more warming and wetter (MW/W), less warming and wetter (LW/W), and central (C) – for two future periods (2020 and 2040) are compared to a current climate base case. (USACE, BPA, and Reclamation 2011).

projected hydrographs. Both features have been present in nearly all studies of PNW hydrologic sensitivity to climatic variation and potential change, and represent the type of vulnerability now being considered in water sector planning.

A number of studies have carried the hydrologic sensitivity analyses forward into assessments of impacts on power generation. In general, the findings reflect the dominant signals from the hydroclimatic analysis, with hydrograph changes largely determining generation changes. Figure 11, for example, conveys the consequences of the hydrologic changes produced by several climate scenarios (wetter and warmer and a central tendency of the future ensemble) for future hydropower in 2020 and 2040. These scenarios expect more hydropower in winter and less in summer, which is consistent with hydrologic effects. These scenarios are akin to sensitivity studies rather than projection-based assessments in that they show single-valued mean system responses to prescribed changes in climate.

5.12.7 The Sustainability of Hydropower in the Pacific Northwest

By the middle of the twenty-first century, the human population is expected to reach 9 billion. Concern is growing that the activities of our current population are already defining a new era that may earn the label of the 'Anthropocene' because of the unprecedented scale of human society's impacts on the Earth's climate and ocean and terrestrial ecosystems. Although potential exists for the mitigation of these impacts as a result of technological progress and increased adoption of conservative or preservative lifestyles, the evidence of the last half-century suggests a greater likelihood that current practices related to the consumption of energy and material resources are likely to persist for the foreseeable future.

If energy demand grows in proportion to population, the present mixture of energy supply, in which 80% of the Earth's electricity is drawn from thermal fuel sources, may be unsustainable given the attendant climate risk, impacts of energy resource development, and energy security consequences. A transition toward greater reliability on renewable energy development is likely to continue as part of a broader strategy to mitigate climatic impacts while meeting energy needs. The environmental community that has historically opposed hydropower for envirosocial reasons supports the new renewables and a diminishing reliance on fossil fuels. This chapter describes the unique and central role that large-scale hydropower plays as the current major source of utility-scale renewable energy, and perhaps more importantly as an energy storage and backup reserve that facilitates the integration of other intermittent renewables into an energy grid. It suggests that along with energy demand and the need for greater renewable sources, the need for hydropower may also grow, leading to changing roles and opportunities for at least some forms of hydropower development.

Yet, will overall hydropower capacity expand significantly or fall because of other constraints? This chapter has described a broad range of forces and phenomena that have shaped the evolution of North American hydropower during the past century, and that color its current outlook. The prospect of future conventional hydropower capacity growth – particularly at large scales, but even at the upper end of the small scale – is undermined by a number of realities. Foremost is that it collides with firmly established opposition rooted in negative perceptions of the environmental and social consequences of hydropower development, many of which are reflected in the regulatory environment for hydropower development and operation. After technological and engineering advances of the Industrial Revolution engendered an era of hydropower expansion, rising awareness of these issues helped to halt hydropower growth in much of the developed world. Although hydropower continues to grow worldwide, with new plants of all scales being constructed in nations of Asia, South America, and Africa, new additions to large-scale capacity in North America and other developed regions such as Europe would require a sea of change in societal values to enable a permissive overhaul of water, energy, and environmental policies.

If hydropower development in regions such as the US PNW were to awaken, however, growth may yet be undermined by a range of phenomena that resist quantification because of their complexity and the limits of current earth system science. The climate, hydrology, and water management communities now grapple with the possibility that the climate, land use, land cover, and associated hydrologic regimes for which we plan and build may not arrive in the future. Hydropower employs infrastructure and operations, management, and planning conventions that were largely designed with the assumption of stationary hydroclimatological parameters, in particular, those determining streamflow; thus, the performance and viability of a hydropower system may depart from expectations if these parameters are realized in ways that exceed planning and design ranges. The hydropower system consequences could include lowered capacity factors or nonoptimal power operations to mitigate poorly quantified flood risks.

Substantial hydroclimatic measurement uncertainties are associated with low-frequency climatic variability, for example, that attributed to the decadal or longer cycles such as the PDO, and the even less well understood fractal scaling dynamics of long-memory processes in climate and watershed systems. Paleoclimatological reconstructions of streamflow records show that low-frequency variability and long-memory processes do, indeed, place substantial portions of natural variability outside the envelope that can be characterized by modern observing system records, which are typically of less than 100 years in length. Nonstationarity can also arise from long-term landscape change, such as large-scale vegetation change, land-use change, forestry and agricultural practices, and glacier change. This chapter summarizes efforts to assess the further possibility that anthropogenic climatic change may alter climate patterns and the hydrologic regime, leading to capacity risk for new and existing plants. Both retrospective assessments and future projections for the PNW favor warmer and wetter future regimes. These are not without impacts and are preferable to drier futures, but warming impacts on the massive natural reservoir represented by the region's snowpack also carries risk. The outlook for existing and new hydropower is sensitive to these diverse sources of variability and change, and a solid quantitative grasp of these sensitivities will be crucial not only for the resilient operation of existing hydroelectric systems but also for effective planning for tomorrow.

Uncertainties regarding the influence of these various geophysical phenomena translate into uncertainty in the prospects for hydropower in the PNW, but only to a degree. Major and arguably more absolute constraints on hydropower development and growth continue to stem from societal values and perceptions that oppose hydropower at large scales required to contribute substantially to a renewable energy in future and thereby mitigate continued growth in energy industry carbon emissions. Despite pressure toward greater acceptance for hydropower (as views on the sustainability and impacts of thermal generation darken and hydropower's role in firming renewable sources is defined), the landscape of PNW hydropower appears likely to evolve modestly at best during the twenty-first century. The United States has developed only 20% of its estimated hydropower potential, and only 2400 of 80 000 dams are powered. Upgrades that add power to existing dams and also new small-scale, pumped storage and hydrokinetic generation will increase overall capacity to some extent.

Over the next century, if opposition to large-scale hydropower does not weaken, the evolution of the US hydropower capacity will reflect a balance between this development and any large-scale hydropower losses – deratings or decommissionings (e.g., as dams fill with sediment, weaken, and become unsafe to operate at present capacity or experience runoff changes for which they cannot effectively reoperate). Rivers will not cease to flow downhill in a region where abundant precipitation falls in the mountains, thus the sustainability of PNW hydropower will to a greater extent be determined by the energy and environmental policy that the society adopts in the future.

Acknowledgments

The authors are grateful for valuable contributions of Dr Sean Fleming toward the discussion of Pacific Northwest climatic variability and change and of long-memory dynamics, as well as for his helpful guidance during the overall preparation of the manuscript.

5.13.1 Introduction

Mainland China has a total terrestrial area of 9.6 million km^2, with a large range of both latitude and longitude. Its topography is characterized by high elevation in the southwest in association with the Qinghai–Tibetan Plateau and low altitude in the east (see Figure 1). Large areas in eastern and southern China are affected by oceanic air currents in summer and by continental air currents in winter, resulting in dry winters and wet summers. Because of geographic and climatic factors, China is vulnerable to severe floods and droughts.

The average annual precipitation in China (see Figure 2) is 650 mm year^{-1} (i.e., 6177.5 billion m^3 year^{-1} in total), which is less than the world land surface average of 800 mm year^{-1}; moreover, the spatial and temporal variations of precipitation are large (Ministry of Water Resources of China 2009). Generally, the precipitation decreases from the southeast coast, with 1800 mm year^{-1}, to the northwest inland, with 50 mm year^{-1} (Figure 2), while the Himalayan Mountains in the southwest are associated with high precipitation. The wet season in southern China lasts from April to September; in the north, it lasts from June to September. The range of the ratios of annual rainfall between a wet year and a dry year for different regions is 2–8, and sequences or clusters of the wet or dry years do occur (Ministry of Water Resources of China 2009).

The total water resources in China amount to approximately 2800 billion m^3 year^{-1}, which accounts for 6% of the world total water resources; the volume of water resources in China ranks sixth in the world, after Brazil, Russia, Canada, USA, and Indonesia (Ministry of Water Resources of China 2009). However, since the population of China reached 1.37 billion in 2010, the average amount of water resources per capita is 2100 m^3 year^{-1} (see Figure 3), which is less than one-third of the world average; this number ranks 121st in the world. Therefore,

Figure 1 Geographic location of China and major river basins.

China has one of the lowest averages of water resources per capita in the world (Ministry of Water Resources of China 2009). Of the annual runoff (2738.8 billion m^3 $year^{-1}$), the minimum basic flow needed for the support of river ecosystems is approximately 867 billion m^3 $year^{-1}$, while flood water (which cannot be used as a water resource) accounts for 1051 billion m^3 $year^{-1}$; hence, the maximum usable volume of water in mainland China is approximately 882 billion m^3 $year^{-1}$, which is 28% of the annual runoff (Wang 2007, 2010).

In mainland China, water resources are unevenly distributed spatially and seasonally. The Qinling Mountains–Huai River line is generally regarded as the geographical dividing line between South and North China (see Figure 1). The average water resources are 560 billion m^3 $year^{-1}$ (1100 m^3 $year^{-1}$ per capita) in South China (including the Yangtze River, the Pearl River, Southeast River basins, and Southwest River basins), and 204.5 billion m^3 $year^{-1}$ (359 m^3 $year^{-1}$ per capita) in North China (including the Songhua River, the Liao River, the Hai River, the Yellow River, and the Huai River); the south is comparatively water rich.

Along with economic development, population growth is the dominant driving force for water demand increase. Figure 4 shows the change in national population and gross domestic product (GDP) in mainland China (National Bureau of Statistics of China 2011) from 1950 to 2010. It is worth noting that the population growth rate in the central and western regions of China is faster than the eastern region for the period from 1978 to 2003 (National Population and Family Planning Commission of China 2007). In 2006, water supply in China was 579.5 billion m^3, with surface water accounting for 81.2% and groundwater 18.4%, respectively (Ministry of Water Resources of China 2006). This was 5.5 times the water consumed in 1949, with an annual increase of approximately 3% over the period from 1949 to 2006. Moreover, in 2007, the amount of water resources per capita was 2156 m^3 $year^{-1}$; this number is expected to decline to 1875 m^3 $year^{-1}$ per capita when the projected peak population reaches 1.5 billion around 2033 (Xie et al. 2009).

Figure 5 shows the categories of water use in 1999 (Ministry of Water Resources of China 1999) and 2008 (Ministry of

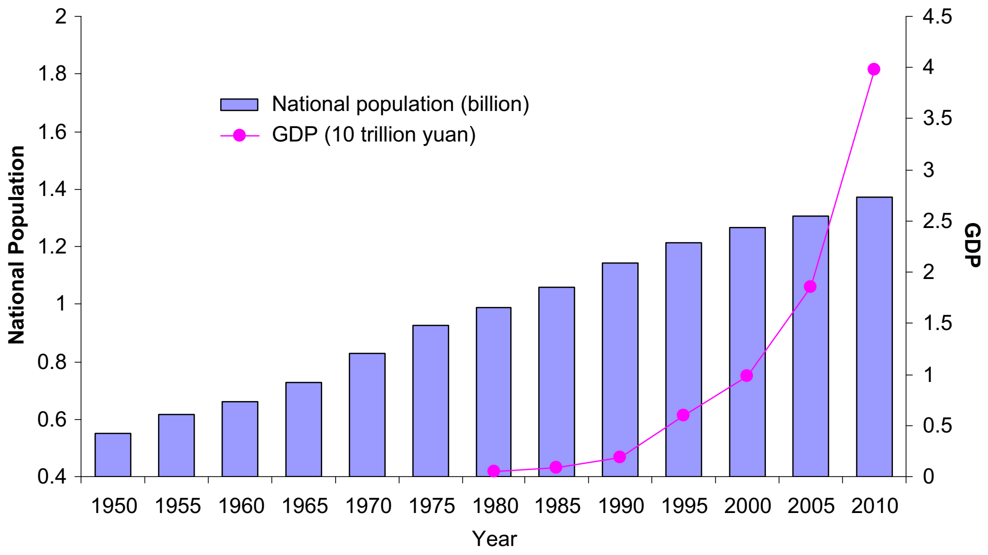

Figure 4 National populations and GDP from 1950 to 2010 in mainland China. Adapted from National Bureau of Statistics of China, 2011: *China Statistic Yearbook*. China Statistics Press.

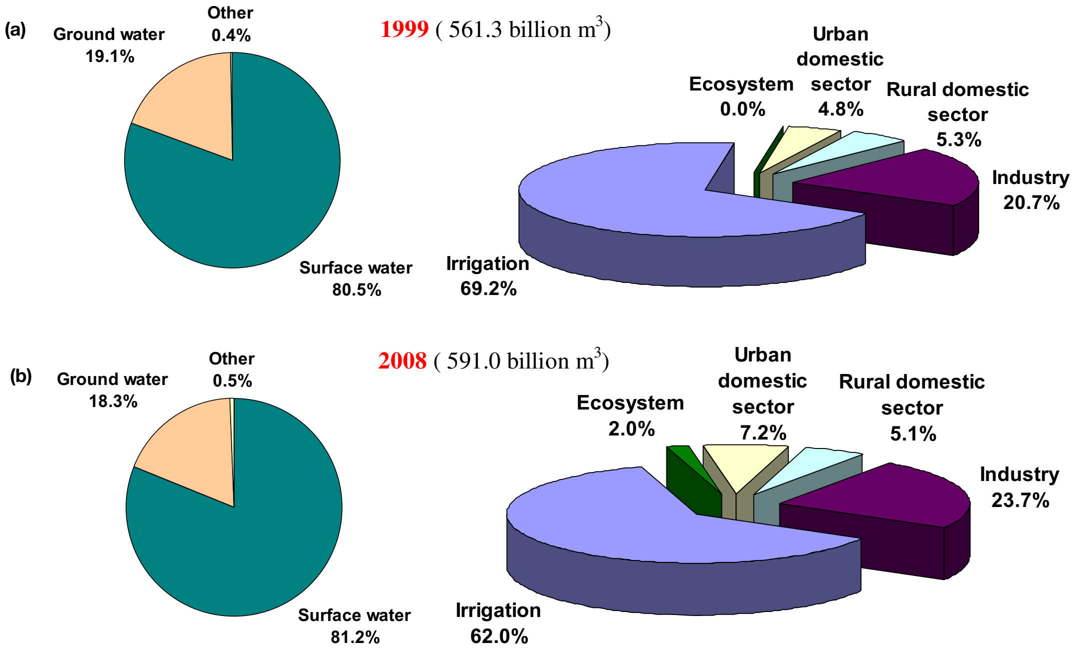

Figure 5 Sources of water supply (left panel) and water use by different sectors (right panel) in mainland China in (a) 1999 and (b) 2008.

Water Resources of China 2008). In both years, irrigation accounts for more than 60% of use; industry is the second largest user and accounts for more than 20% of water used. The ratios of water use for urban domestic and industry sectors in 2008 are 3% larger than those in 1999. Therefore, urbanization has become another factor driving the water demand increase; it is expected that the urban domestic water demand will further increase because the urban population will reach 55–66% of total national population by 2020 (Xie et al. 2009). The continuous growth of China's population and economy, leading to higher water demand and associated water-related environmental issues, makes the study of water resource vulnerability extremely important. The possibility of further changes in climate provides a further imperative of exploring and understanding the characteristics of water resources in mainland China.

5.13.2 Water Resource Status in Seven River Basins

There are more than 50 000 rivers in China with drainage basin areas larger than 100 km^2; of these, more than 1500 have basin

Table 1 The seven major rivers in mainland China (Qian 1994)

River	*Length (km)*	*Basin area (km^2)*	*River's destination*	*Population in 2004 or 2005 (millions)*
Yangtze River	6397	1 808 500	East China Sea	440
Yellow River	5464	752 443	Bohai Gulf	113
Songhua River	2308	557 180	Heilong River	62
Pearl River	2214	453 690	South China Sea	99
Huai River	1000	269 283	Yangtze River and Yellow Sea	172
Hai River	1090	263 631	Bohai Gulf	130
Liao River	1345	228 960	Bohai Gulf	35

areas larger than 1000 km^2. Most rivers in China are fed by rainfall, and some rivers are partly fed by snow or glacier melting water. The seven major rivers in mainland China are the Yangtze River, the Yellow River, the Songhua River, the Pearl River, the Huai River, the Hai River, and the Liao River (see **Figure 1**). **Table 1** lists the basic hydrological information of these seven river basins. Note that city names, river gauge station names, and dam names given in the following text are marked in **Figures 1 and 9–11**.

The total area of the seven major river basins (the Yangtze River, the Yellow River, the Songhua River, the Pearl River, the Huai River, the Hai River, and the Liao River) is approximately 45% of the total land area of mainland China (see **Figure 1**). However, the volume of water resources of these basins is approximately 64% of the country's total, with approximately 80% of the total population living there. **Table 2** lists the basic information on the water resource status of these seven river basins; the amounts of annual water resources per capita are calculated based on the population in 2004 for the Pearl River basin and 2005 for other six basins. The threats of water shortage over the Hai River, the Huai River, and the Yellow River basins are obvious (**Table 2**). The following sections briefly introduce the seven river basins one by one.

5.13.2.1 Yangtze River

The Yangtze River is the largest river (in terms of the length, basin area, and streamflow volume; see **Table 1**) in China and the third longest river in the world. The basin area is 1.8 million km^2 and the length of the mainstem is 6397 km. The Yangtze River basin runs through 19 provinces (including autonomous regions and municipalities), namely Qinghai, Tibet, Sichuan, Gansu, Shaanxi, Yunnan, Chongqing, Guizhou, Guangxi, Guangdong, Hubei, Hunan, Henan, Anhui, Jiangxi, Zhejiang, Fujian, Jiangsu, and Shanghai (see **Figures 1 and 2**). There are many tributaries, such as the Min River, the Wu River, the Xiang River, the Han River, the Huangpu River, and so on; among them, the Han River is the longest one. The Qutang Gorge, Wuxia Gorge, and Xiling Gorge of the river are known as the Three Gorges (*Sanxia* in Chinese). The population over the basin reached 0.44 billion in 2005, which is more than 30% of the total national population of China. The river basin is located mainly in subtropical climate zones, and seasonal and interannual variations of the runoff in the mainstem are large. As an agricultural production base, the rice product in the basin accounts for up to 70% of the total in China. The potential hydropower capacity of the river reaches 250 000 Million Watts (MW). The river has abundant fish resources, with about 500 fish species. Consequently, the water resources in the Yangtze River basin make a great contribution to the agricultural and economic development in mainland China.

The streamflow of the Yangtze River is relatively stable (Lu 2004). Nevertheless, the Yangtze River basin is vulnerable to floods and droughts, especially in its middle stream and downstream regions. For example, a serious flood that occurred in 1998 over the entire river basin submerged an area of more than 0.2 million km^2 and caused an economic loss of 166 billion RMB Yuan (about US$ 20 billion in 1998 equivalent) (Yin and Li 2001). The drought that occurred in 2011 in the middle and lower reaches of the river was the worst since 1961; the economic loss due to the 2011 drought was 14.9 billion RMB Yuan (about US$ 2.3 billion in 2011 equivalent), and the farmland affected totaled 40 000 km^2.

5.13.2.2 Yellow River

The Yellow River is the second largest river in terms of both the basin area (752 443 km^2) and length (5464 km) in China. The river runs through Qinghai, Gansu, Sichuan, Ningxia, Inner Mongolia, Shanxi, Shaanxi, Henan, and Shandong provinces

Table 2 Status of water resources in the seven major river basins (Qian 1994)

	Annual precipitation		*Annual river runoff*				
River	*Amount (km^3 year^{-1})*	*Depth (mm year^{-1})*	*Amount (km^3 year^{-1})*	*Depth (mm year^{-1})*	*Annual groundwater (km^3 year^{-1})*	*Annual total water resources (km^3 year^{-1})*	*Annual water resources (m^3 year^{-1}) per capita*
Yangtze	1936	1071	951	526	246	961	2181
Yellow	369	464	66	83	41	74	655
Songhua	279	500	74	133	12	88	1419
Pearl	897	1544	336	741	112	471	4758
Huai	283	860	74	225	39	96	558
Hai	178	560	29	91	27	42	323
Liao	190	551	49	141	19	58	1657

(see **Figures 1 and 2**). The population in 2005 over the basin was about 0.113 billion. The river is well known worldwide due to soil erosion and sediment problems. Most of the river streamflow comes from upstream Lanzhou City. The runoff yield decreases downstream from Lanzhou City to Hekouzhen station due to the evaporation and leakage losses. The runoff yield increases in the region from Hekouzhen station to Taohuayuan station. However, from Huayuankou station to the river outlet, there are significant water losses along the river channel; the river bed in this part is higher than the surrounding land surface, resulting in a so-called suspended river. This suspended river raises the vulnerability of the region to floods.

In 1958, the river reach between Sanmenxia and Huayuankou stations experienced the worst flood since 1919; the Beijing–Guangzhou railway, which is the main transport route in mainland China, was interrupted for 14 days. In addition, based on the historical records, the Huayuankou station for the period of 1946–88 and the Sanmenxia station for the period of 1953–88 experienced decreasing trends of the annual mean and annual maximum discharge (Lu 2004). On the other hand, because the western and northern parts of the river are located in arid and semi-arid areas, where the annual rainfall is less than 250 mm year^{-1}, basinwide droughts are easily triggered. Furthermore, for the period of 1972–97, the downstream area of the river suffered from dried-up river courses; in 1997, such a situation lasted 226 days, and the annual economic loss was more than 1.1 billion RMB Yuan (about US$ 0.13 billion in 1997 equivalent). This dry situation also brought many other environmental and ecological problems, such as land desertification, aquatic ecosystem stress, water quality degradation, and so on.

5.13.2.3 Songhua River

The source of the Songhua River is the Tianchi Lake on Changbai Mountain. The basin area is 557 180 km^2, and the length is 2308 km (**Table 2**). The population over the basin was 62 million in 2005. As it is located at the mid-temperate climate zone, evapotranspiration is relatively low. The Songhua River at Harbin station experienced an increasing trend of the annual minimum discharge for the period of 1898–1987 (Lu 2004). Since 1950, floods have occurred in 1953, 1956, 1957, 1960, 1969, and 1998. For the 1957 flood, high-intensity rainfalls occurred in July and August, and the number of days with continuous rainfall reached 45. About 4 million people were affected and 81 people died. The economic loss was 0.24 billion RMB Yuan (about US$ 0.1 billion in 1957 equivalent). In 1998, the river experienced another serious flood; the maximum water level reached 120.89 m and the associated discharge was 16 600 $\text{m}^3\,\text{s}^{-1}$ at Harbin station on August 22. For the basin, this flood was the worst in the twentieth century. On the other hand, during the period of 2000–03, the mainstem of the Songhua River endured severe low water levels (the lowest being 110.07 m at Harbin station), and the droughts resulted in the reduction of industrial and agricultural outputs.

5.13.2.4 Pearl River

The total basin area of the Pearl River is 453 690 km^2 (part of the river basin, 11 590 km^2, is located in Vietnam), and the length of the mainstem is 2214 km. The population over the basin was 99.35 million in 2004. The Pearl River is situated in a tropical to subtropical monsoon climate region. The average runoff is 336 $\text{km}^3\,\text{year}^{-1}$, making it the second largest river in terms of streamflow volume in China; the annual runoff generation rate (about $0.74 \times 10^6\,\text{m}^3\,\text{year}^{-1}$) is the highest among the seven major rivers in China. A decreasing trend has been identified for annual minimum discharge at Wuzhou station for the period of 1915–84 (Lu 2004).

Historically, the basin has suffered from frequent floods and most of the river's major tributaries have experienced severe floods (e.g., 1979 flood in the East River, 1982 flood in the North River, and 1998 flood in the West River); serious basinwide floods also occurred in 1915, 1968, 1994, and 2005. For the period of 1990–2005, the total economic loss over the basin caused by floods reached 345 billion RMB Yuan (about US$ 41.7 billion in 1998 equivalent). Droughts also frequently occur over the basin, especially for the southwest region (e.g., severe droughts occurred in 1963 and 2010). In addition, due to the droughts, persistent seawater intrusion has threatened freshwater supply in the Pearl River delta.

5.13.2.5 Huai River

The Huai River basin area is 269 283 km^2, and the mainstem length is 1000 km. The Huai River runs through Henan, Hubei, Anhui, Shandong, and Jiangsu provinces (**Figures 1 and 2**). The river in the lower reach has three branches. One enters into the Yangtze River at Sanjiangying station near Yangzhou City in Jiangsu province; another enters into the Yellow Sea through the North Jiangsu Irrigation Canal; the third one flows into Haizhou Bay through the Huaishu River (a comprehensive water resource utilization project). The total population over the basin was 0.172 billion in 2005. The average population density is about 639 per km^2, ranking first among the seven major river basins in China (Huai 2011). The Huai River at Bengbu station showed a decreasing trend in the annual minimum discharge for the period of 1915–86 (Lu 2004). Due to the significantly changed geography of the Huai River basin in history, water flow in the middle stream cannot easily flow into the downstream region.

Water-related hazards, such as floods and droughts, have frequently occurred in the basin. From 450 CE (Common Era) to 1950, on average, there were 94 floods per century over the basin; droughts occurred 260 times, with a frequency of 1 per 1.7 years (Hai 2011). In the 1991 flood, the area of farmland inundated was 55 160 km^2, and the population affected was 54.23 million. The economic loss in 1991 was 34 billion RMB Yuan (about US$ 6.39 billion in 1991 equivalent). Two severe droughts occurred in 1966 and 1978, associated with an annual average rainfall of 579 mm and 601 mm, respectively, compared to 911 mm year^{-1} for the long-term average; the area affected by each of the droughts was about 33 330 km^2.

5.13.2.6 Hai River

The basin area of the Hai River is 263 631 km^2, with the length of mainstem of 1090 km. It is located in semi-arid and semi-humid areas. There are 25 large- and medium-scale cities in the basin, including Beijing and Tianjin, and the total population over the basin reached 0.13 billion in 2005. The average population density is about 410 per km^2 (Hai 2011). The streamflow volume has greatly decreased since 1980. Due to the serious overexploitation of groundwater, large-scale land subsidence has occurred in the downstream area of the basin. Also, many tributaries are dry for most of the year. Meanwhile, water pollution has worsened in conjunction with the reduced streamflow.

5.13.2.7 Liao River

The Liao River has a basin area of 228 960 km^2, and a mainstem length of 1345 km. The total population over the basin was 35 million in 2005. The basin area and annual runoff (14.8 km^3 year^{-1}) are the smallest among the seven major rivers in China. The Liao River has a high sediment load because many parts of the river flow through powdery loess, which is ranked third behind the Yellow River and Hai River. A decreasing trend of annual mean discharge has been observed at Xiaoheyan station in the Liao River for the period of 1955–98 (Ren et al. 2002). During the past 100 years, 50 floods occurred over the basin; drought events occurred almost every year in the east of the basin (i.e., the Xiliao River basin). In the 2005 flood, 1.34 million people were affected and 1400 km^2 of farmland was inundated; the economic loss was 7.4 billion RMB Yuan (about US$ 0.92 billion in 2005 equivalent).

5.13.3 Some Key Water Resource Issues

Since 1949, more than 51 extreme floods and 18 widespread and severe droughts have occurred in mainland China. Floods and droughts in China are high frequency, with large spatial extent as well as heavy losses of life and societal property. Specifically, the Yellow River delta, the Yangtze River delta, and the Pearl River delta are vulnerable to storm surge, seawater intrusion, coastal flooding, shoreline erosion, and loss of wetlands. Other water resource issues in mainland China include water environment deterioration, soil erosion, river sedimentation, and groundwater overdraft. In the previous section, some water resource issues in the seven major river basins were introduced. The following sections will review some key water-related issues in mainland China.

5.13.3.1 Floods

Floods are one of the most serious disasters frequently occurring in China. Due to the great variation in meteorological, topographical, and geological features over the territory, about two-thirds of the land area of China is subjected to different types of floods. Table 3 lists the distribution features of historical floods in mainland China.

The continental monsoon climate influences most of China. Rainfall in the territory is mainly formed by two types of weather systems (Qian 1994). The first is the westerlies rain belt system, including fronts, extratropical cyclones, tangential lines, and low vortexes. The other is the low-latitude tropical weather system, which includes mostly tropical cyclones and typhoons. The principal source of flood disasters in China is rainstorm floods; other types of floods include snow melt floods, glacier ice melt floods, and the floods caused by storm surges in coastal regions.

Table 3 Statistical information of floods occurring in the period of 1840–1949 (Flood Control and Drought Relief Headquarters, and Nanjing Research Institute of Hydrology and Water Resources (FCDRH and NJRIHWR) 1997)

Spatial coverage	*Number of years*	*Percentage %*
Whole country	4	3.6
North and south	6	5.5
Central	25	22.7
North	15	13.6
South	1	1.0
Other regions	59	53.6
Total	110	100

Generally, in mainland China, flood disasters in the eastern region are mainly caused by rainstorms and coastal storm surges. The western region is primarily subject to mixed-type floods from snow and glacier melting and local rainstorms. The economically developed eastern and southern parts (see Figure 2), which possess approximately 35% of the national cultivated land, 70% of the national agricultural and industrial products, and more than 50% of the national population, are most seriously threatened by floods (Wang 2010).

The total loss caused by floods in China was approximately 1.5% of the GDP for the period of 1990–2010 (Liu 2009). For example, in 1998, 4185 people lost their lives in mainland China due to the unusually high rainfall in the wet season (World Socialist 2005). In 2005, 1660 people were killed in the flood season (National Bureau of Statistics of China 2006). In 2007, 177 million people were affected by the nationwide floods, resulting in more than 1200 deaths, 0.12 million km^2 of croplands ruined, and more than 1 million houses destroyed; the direct economic loss was over 100 billion RMB Yuan (US$ 12.82 billion in 2007 equivalent) (National Bureau of Statistics of China 2008).

5.13.3.2 Droughts

In normal years, due to huge water demands from various water consumption sectors in mainland China, water shortage is 25 billion m^3, accounting for 4% of the national total demand. In dry years, the water shortage can reach 30–40 billion m^3, which is 6% of the total demand. Three-quarters of the national water shortage occurs in North China, and the region with the worst water shortage is the Hai River basin. In the Hai River basin, the situation has been deteriorating since the 1950s, becoming severe since 1980 as reflected in the record of annual runoff (see Figure 6).

The total loss resulting from drought disasters in mainland China was about 1% of the GDP for the period of 1990–2010, or about 300 billion RMB Yuan (about US$ 36.23 billion in 2000 equivalent) (The Ministry of Water Resources 2010). Table 4 lists the statistical information (Flood Control and Drought Relief Headquarters, and Nanjing Research Institute of Hydrology and Water Resources (FCDRH and NJRIHWR) 1997) of drought disasters on agriculture in different river basins; it shows that the drought-influenced areas and drought-resulted damages in the basins of the northern region are normally much higher than in the Pearl River in the southern region. During the periods of 1949–90 and 1971–90, the

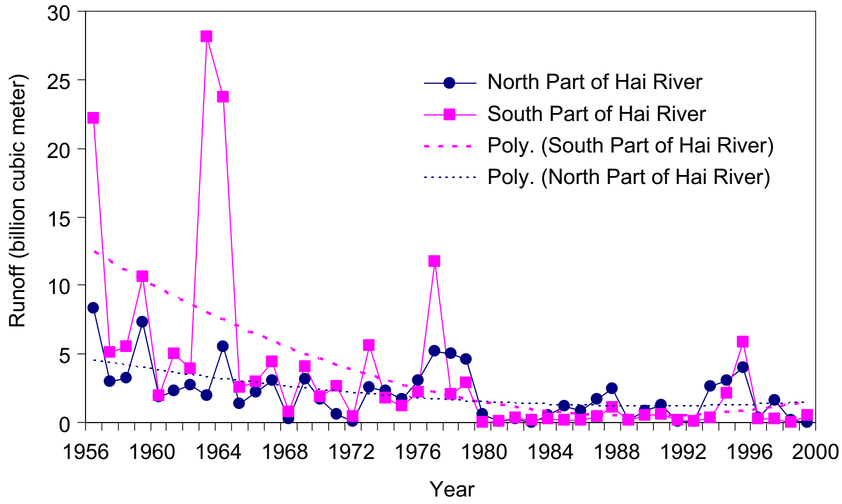

Figure 6 Annual runoff variations in the Hai River. Adapted from Shen, D. J., 2010: Climate change and water resources: evidence and estimate in China. *Curr. Sci.*, **98**, 8.

highest drought impact in northern China occurred in the Yellow River basin, followed in decreasing order by the Songhua River, the Liao River, the Huai River, and the Hai River (FCDRH and NJRIHWR, 1997).

In 2010, southwest China (including Yunnan, Sichuan, and Guizhou provinces, Guangxi Zhuang autonomous region, and Chongqing municipality) suffered from the worst drought in six decades; it lasted 6 months and resulted in serious drinking water shortages and crop damages. According to statistics from the China Foundation for Poverty Alleviation (CFPA), the direct economic loss of the drought was more than 35 billion RMB Yuan (about US$ 5.12 billion in 2010 equivalent), and more than 2 million people were reduced to poverty levels. The drought affected about 5000 km^2 of natural reserves, and shrinking wetlands and water shortages for wildlife were reported by the Yunnan provincial forestry bureau (China Daily 2010). In 2011, the worst drought in 50 years hit the midstream and downstream areas of the Yangtze River basin. Precipitation in the regions (including the Anhui, Jiangsu, Hubei, Hunan, Jiangxi, and Zhejiang provinces and Shanghai municipality) was 30–80% less than that in normal years. The surface area of the largest freshwater lake in mainland China, Poyang Lake in Jiangxi province, shrank to just 16% of its average.

The difference between areas of cropland damaged (referring to where the crop production is reduced by more than 30%) and areas of agriculture affected (referring to where crop production is reduced by more than 10%) by droughts depends not only on the variation of meteorological conditions, but also the irrigation efficiency and the irrigation intensity of farmlands. The ratio of cropland damaged to total agriculture area affected in northern China is more than 0.5, while the ratio in the Pearl River basin in the southern China is less than 0.4 (FCDRH and NJRIHWR 1997). Moreover, Ge et al. (2011) estimated the water footprint for each province (or autonomous region) in mainland China, in which the water footprint is defined as the total volume of freshwater consumed for producing the goods and services (Hoekstra et al. 2009). With reference to the water footprint, the extent of water shortage in Tianjin, Beijing, and Shanghai municipalities, Ningxia autonomous region, and Hebei and Shanxi provinces are the worst in mainland China.

5.13.3.3 Soil Erosion

Soil erosion is an important factor in influencing river sedimentation and water quality. The total eroded area in China amounts to one-sixth of the territory (Qian 1994). A large amount of fertile soil from farmlands is eroded and transported into the rivers and seas. The eroded areas are mainly found in the Loess Plateau in North China, the Yunnan–Guizhou

Table 4 Droughts over the major river basins (FCDRH and NJRIHWR 1997)

	Average during 1949–90			*Agriculture affected rate*		*Crop damaged rate*

Yellow	16.2	11.3	1.5	33.6	1987	27.0	1987
Yangtze	10.3	5.6	0.8	26.1	1959	15.7	1978
Pearl	9.6	4.0	0.8	26.1	1988	18.6	1963

Plateau in southwest China, and the hilly and mountainous regions in South China (Figure 2). The area of the Loess Plateau is 340 000 km^2 with an annual precipitation ranging from 300 to 600 mm year^{-1}. Within the loess area, the gullied plateau regions and the gullied-hilly regions, amounting to 250 000 km^2, have the highest erosion rates. Due to the high storm intensity, sparse vegetation cover, and steep slopes, soil erosion in the Loess Plateau is rampant and results in a distinctive geomorphological landscape (Qian 1994). The erosion rate ranges from 5000 to 10 000 t km^{-2} year^{-1} on slopes and from 15 000 to 20 000 t km^{-2} year^{-1} in gullies. The Karst region of the Yunnan–Guizhou plateau with an eroded area of about 340 000 km^2 is another region of extensive erosion, and it has an annual precipitation of 1000 mm year^{-1}.

Eroded areas account for about 54% of the Yellow River basin, with a normal surface area erosion rate of 2500 t km^{-2} year^{-1}. Based on sediment transport observations, the most seriously eroded area in the Loess Plateau has an erosion rate of 5000–8000 t km^{-2} year^{-1}, which is the highest in China and the main source area for sediment in the Yellow River basin. In the Yangtze River basin, the eroded area is about 570 000 km^2, and the annual soil loss is about 3500 to 4000 t km^{-2} year^{-1}. The region of most serious erosion is in the upper stream of the Yangtze River, from Dukou City to Yichang City. The eroded areas in the Hai River, the Huai River, the Songhua River, and the Liao River basins are about 104 000 km^2, 56 000 km^2, 180 000 km^2, 128 000 km^2, and 59 000 km^2, respectively. Overall, soil erosion is a serious issue in sustaining water resource security in mainland China, and measures for protecting the land surface and preventing soil erosion are necessary. To this end, there are numerous engineering projects implemented in mainland China. For example, the Grain-for-Green project for western China took off in 2000; the project aims to turn low-yielding farmland back into forest and pasture to reduce soil erosion and restore ecological balance in the western region.

5.13.3.4 River Sedimentation

Over 40 rivers in China carry a large amount of sediment due to severe soil erosion, and each of them has an annual sediment load of over 10 million t year^{-1}. Data for the seven major rivers and some other rivers in southwest China and inland rivers (Qian 1994) reveal that the average annual sediment load totals 2.687 billion t year^{-1}. The main sediment problems include reservoir sedimentation, sediment at low water head hydro projects and in canal systems, sediment in rivers and lakes, sedimentation in estuaries and below tidal barriers, and abrasion of high-energy particle turbines and hydraulic structures by sediment particles.

The annual sediment load transported by the Yellow River is about 1.6 billion t year^{-1}, and the riverbeds in the downstream areas are raised at a rate of 0.06–0.10 m year^{-1} due to the huge amount of sediment (Qian 1994). This threatens the river bank safety during the flood season. Above the Hekouzhen station, the catchment area is 360 000 km^2, and the sediment yield accounts for 9% of the total, while the runoff yield accounts for 53% of the total. The area between Hekouzhen and Longmen stations is 130 000 km^2, and the runoff yield is about 15% of the total, while the sediment yield can reach up to 56% of the river total sediments; it is this area that is the main sediment source in the Yellow River basin.

5.13.3.5 Water Quality

Of the 20 most seriously water-polluted cities in the world, 16 are located in mainland China. Most of the major river basins suffer from severe pollution (Gleick et al. 2008), and about 300 million people have no access to safe water. Table 5 lists the growth rates of water use for the industrial and urban domestic sectors in China since the 1980s. The increase of water use can reflect the growth of wastewater discharge and water pollution.

The main features of the water pollution in China are a large volume of wastewater discharge, little treatment, and an increasing trend of pollution. During the period of 1980–2000, the growth rates of wastewater discharge from the domestic sector and industry were 7.1% per year and 5.3% per year, respectively (Wang 2010). In 2006, the wastewater discharge was about 74.1 billion m^3 year^{-1}, while the treatment rate was 57% in urban areas and only 23% in rural areas. In 2010, the chemical oxygen demand loading to rivers was 30.29 million t year^{-1}; NH_3-N, total nitrogen, and total phosphorus in mainland China discharged into rivers amounted to 1.73, 4.73, and 0.42 million t year^{-1}, respectively (National Bureau of Statistics of China 2010).

Following the Chinese National standard for grading water quality, Grades I, II, and III of water are potable and Grades IV and V are acceptable for use by industry and agriculture. For the 2.8 million km of overall river length in mainland China, about 34% has water quality graded as worse than Grade IV (see Figure 7). Regarding the groundwater quality, of the assessment area of 1.97 million km^2, about 63% of the water quality is grade IV or V (Wang 2010).

5.13.3.6 Groundwater Overdrafting

Around half of all of China's wheat is produced in North China, where the water shortage is severe; consequently, groundwater is pumped out to irrigate the croplands. Therefore, groundwater overdrafting is a very common issue in North China, and in some regions it becomes a very serious problem. For example, the groundwater exploitation in Hebei province was 13 billion m^3 year^{-1} in the 1980s, with groundwater table depths of 170–350 m. In the 1990s, the amount was 16 billion m^3 year^{-1}, with water table depths of

Table 5 Growth rates (%) of water use for the industry and urban domestic sectors in China since 1980 (Wang 2010)

Sector	*1980–85*	*1985–90*	*1990–95*	*1995–2000*	*2000–06*	*1980–2006*

II	106 781
III	61 765
IV	33 304
V	17 925
Worse than V	45 552

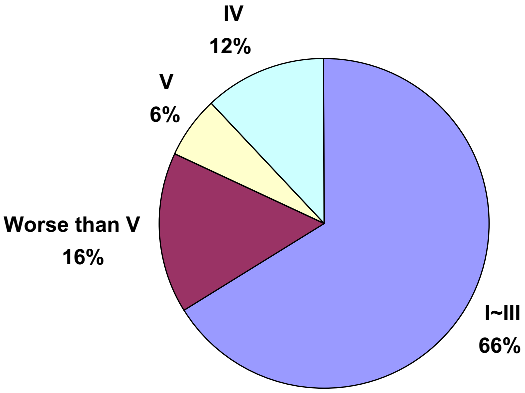

Figure 7 Surface water quality in mainland China in 2006. Adapted from Wang, H., 2010: *Water Resources Challenges and Policies in China*. Public Lecture, Hong Kong.

250–380 m (Shao and Hu 2002). Another consequence of groundwater overdrafting is loss of wetlands. It is reported that 90% of the wetlands in Hebe province have disappeared since 1960, and streams and creeks have been dried up. The largest natural freshwater lake in the Hai River basin, Baiyandian Lake, is losing area and becoming grossly polluted (Griffiths 2006). Regarding urban areas, groundwater overdrafting in the cities of Shanghai (Wei 2006), Beijing (Zhang and Kennedy 2006) and Tianjin (Bai and Imura 2001), for example, resulted in declines of the water tables and groundwater storage. Land subsidence (Yin et al. 2006; Zhang et al. 2008) has occurred in urban areas in association with groundwater overdrafting.

5.13.4 Possible Influences of Climate on Water Resources

A temperature increase in China over the past five decades (Piao et al. 2010) has been observed. There are serious potential vulnerabilities to China's agricultural production due to climate variations; however, no definitive conclusion can be drawn due to the uncertainties involved in climate change projection. It is possible that China's average temperature will increase further by 1–5 °C by 2100 (Meehl et al. 2007), whilst summers are likely to be much warmer (Piao et al. 2010).

5.13.4.1 Observed Climate Variations

Over the Yangtze River basin, the western, eastern, and northern parts show more well-developed increasing trends for the temperature than the southern region for the past 100 years (before 2007) (National Development and Reform Commission of China 2007). There is a seasonality to warming, with the most pronounced temperature increase occurring in winter, especially for the period of 1986–2005 (National Development and Reform Commission of China 2007), with warming in winter (0.04 °C per year) being about four times the rate of warming in summer (0.01 °C per year). Meanwhile, the warming in northern China is faster than that in southern China.

There is no obvious trend on the annual precipitation in the past 100 years in mainland China (National Development and Reform Commission of China 2007). However, since the 1950s, the annual precipitation has gradually decreased, with an average rate of 2.9 mm per decade, while regional variation is noticeable. The most obvious decease of precipitation occurred mostly in northern China and also in the eastern parts of northwestern and northeastern China, with an average rate of 20–40 mm per decade. Meanwhile, the precipitation significantly increased in southern China and southwestern China, with an average rate of 20–60 mm per decade.

The urbanization-induced temporal warming at the two stations of Beijing and Wuhan cities was analyzed (Ren et al. 2007). The study concluded that the annual urban warming accounted for 61.3 and 39.5% of overall warming in the respective cities for the period of 1981–2000. Zhou et al. estimated that the warming of mean surface temperature of 0.05 °C per decade is attributed to urbanization in Southeast China for the period of 1979–98 (Zhou et al. 2004). The local urbanization effects on weather variables in South China have also been studied (Chen et al. 2011). It was found that for the period of 1960–2005 the variations of weather variables before and after 1984 are different. Before 1984, there were no significant urbanization effects, and the daily minimum temperature ($T_{\min}$), relative humidity (RH), and precipitation (P) steadily increased but the daily maximum temperature ($T_{\max}$) decreased, resulting in a considerable decrease in the diurnal temperature range (DTR) and a slight decrease in the surface temperature. After 1984, $T_{\min}$ and $T_{\max}$ increased considerably, and an urbanization influence on $T_{\min}$, but not $T_{\max}$, is observable. The urbanization effect causes an additional increasing trend in $T_{\min}$ with a rate of about 0.6 °C/decade, and also results in a decreasing trend in both DTR and RH in the urban area. The urbanization influence results in a near-uniform increase of $T_{\min}$ for all four seasons and a strong decrease of RH in summer and autumn. Moreover, there is no significant change in precipitation at the annual scale, but an increasing rate of 11.8% per decade in summer was detected (Chen et al. 2011). With the urbanization influence, a considerable increase in precipitation is noticeable at the annual scale; specifically, the increasing rates of 18.6% per decade in summer and 13.5% per decade in autumn are observed.

5.13.4.2 Temporal Change of Water Resources

The Ministry of Water Resources in mainland China assessed the situation for water resources over two periods, 1956–79

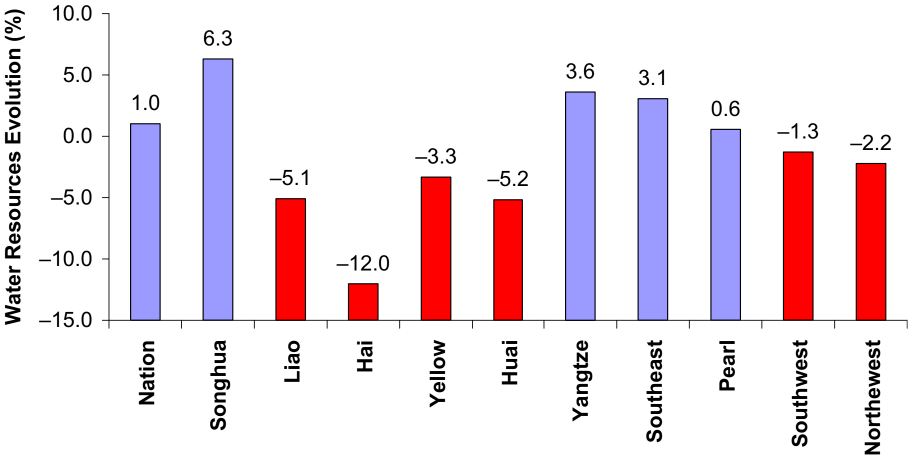

Figure 8 Water resource evolution between 1956–79 and 1980–2000 in mainland China and different river basins. Adapted from Wang, H., 2010: *Water Resources Challenges and Policies in China*. Public Lecture, Hong Kong.

and 1980–2000. It was found that the precipitation was 10% less, 6.9% less, and 2.6% less in the second period compared with the first period in the Hai River basin, the Yellow River basin, and the Liao River basin, respectively. In contrast, the precipitation was 3, 4.6, 2.6, and 6.5% more in the second period in the Yangtze River, the Songhua River, and the two river basins in southeastern and northwestern China, respectively. Except for the Songhua River basin and the rivers in southwestern China, the annual average potential evaporation was 5.4% less in the second period than in the first period. Shen (2010) indicated that the main reasons for the potential evaporation decrease between the two periods were the change of sunshine percentage, wind speed, and increase in air humidity during the second period.

From the assessment of the Ministry of Water Resources, the surface water resources and total water resources in mainland China have increased slightly in the second period, corresponding to the slight increase in precipitation. However, there are spatial differences as reflected by the various river basins, and Figure 8 shows the change in water resources for the two periods 1956–79 and 1980–2000. In the second period, total water resources in southern China increased by 5%; however, the water resources in northern China have clearly decreased, especially for the Yellow River basin, the Hai River basin, and the Liao River basin (Shen 2010). In the Hai River basin, there was a 10% decrease in precipitation, 41% decrease in runoff, and 25% decrease in total water resources. In the Shandong Peninsula of the Huai River basin, there was a 16% decrease in precipitation, 51% decrease in runoff, and 34% decrease in total water resources. Shen indicated that the reason for the water resource decrease in north China is the reduction in precipitation and landscape change (Shen 2010). Comparing the current land covers with those of 50 years ago, 35% of the areas in the Yellow River, Huai River, Hai River, and Liao River basins have been changed; generally, the runoff is decreased by 10–20% in normal precipitation years and by 15–40% in dry years (Shen 2010).

Over mainland China, the analysis of the past weather data revealed that heavy rainfall events happened more frequently over northwestern China and in the middle and downstream areas of the Yangtze River, but not in northeastern China (Zhai et al. 2005). There is a general decrease in terms of rainy days across the country (Piao et al. 2010). The Yellow River is sensitive to drying trends. A persistent decrease in runoff is observed. This is attributed to both climate impacts and overextraction of water for irrigation, industry, and domestic usages. There has been a small increase (not statistically significant) in annual runoff for the Yangtze River since 1960 (Piao et al. 2010). A decrease in runoff has occurred in many gauged headwater catchments in the autumn, whilst a positive runoff trend is observed for the midstream and downstream sections of the Yangtze River, owing to the increasing precipitation in this region. Northwestern China, especially the arid area, has experienced a decline in the occurrence of severe drought, which is evidenced by both rising lake levels and increasing vegetation cover in areas adjacent to deserts (Piao et al. 2010).

5.13.4.3 Glacier Melting

China has 46 377 glaciers, with a total area of 59 425 km^2 (Li et al. 2008). The glaciers shrank by 7%, which is equal to 3790 km^2, in the Qinghai-Tibetan Plateau in the past four decades (Li et al. 2008). The runoff owing to the glacier melting has increased from 62 km^3 in 1980 to 66–68 km^3 in 2000 (Li et al. 2008). Piao et al. (2010) presented a case study of glacier retreat and melting influence in the Tarim River basin in Northwest China, showing that the melting of glacier has increased the local runoff by 15% between 1957 and 2000; however, due to rapid development of oases in the basin, the increased runoff can not satisfy the water demand (Hao et al. 2008), and the runoff in the Tarim river mainstem has decreased. Gurung et al. (2011) indicated that changes in snow cover for the western Himalaya are primarily due to interannual variations in circulation patterns as there is the correlation between the amount of annual snowfall and annual seasonal snow cover.

Warming in spring and early summer would increase runoff due to glacier melting (Barnett et al. 2005; Liu et al. 2009). Nevertheless, the vulnerability of the glaciers to the warming in

mainland China is still uncertain. Generally, about 5–27 and 10–67% of glacial areas are projected by some researchers to melt by 2050 and 2100, respectively (Shi and Liu 2000; Xie et al. 2006); they project that glacier melt peak would occur during the period of 2030–2050 (Xie et al. 2006; Chen et al. 2005). According to the China Meteorological Bureau, all small glaciers less than 2 km^2 would disappear if the temperature increased by 1.9–2.3 °C in northwest China.

5.13.4.4 Future Water Resources

Future projections of climate claim a large range of uncertainty on the question of whether northeastern China will continue to confront droughts in the future (Piao et al. 2010). A decrease of drought in northwestern China is projected under the Intergovernmental Panel on Climate Change (IPCC) B1 scenario (Nakićenović and Swart 2000), while the bipolarity of a drier

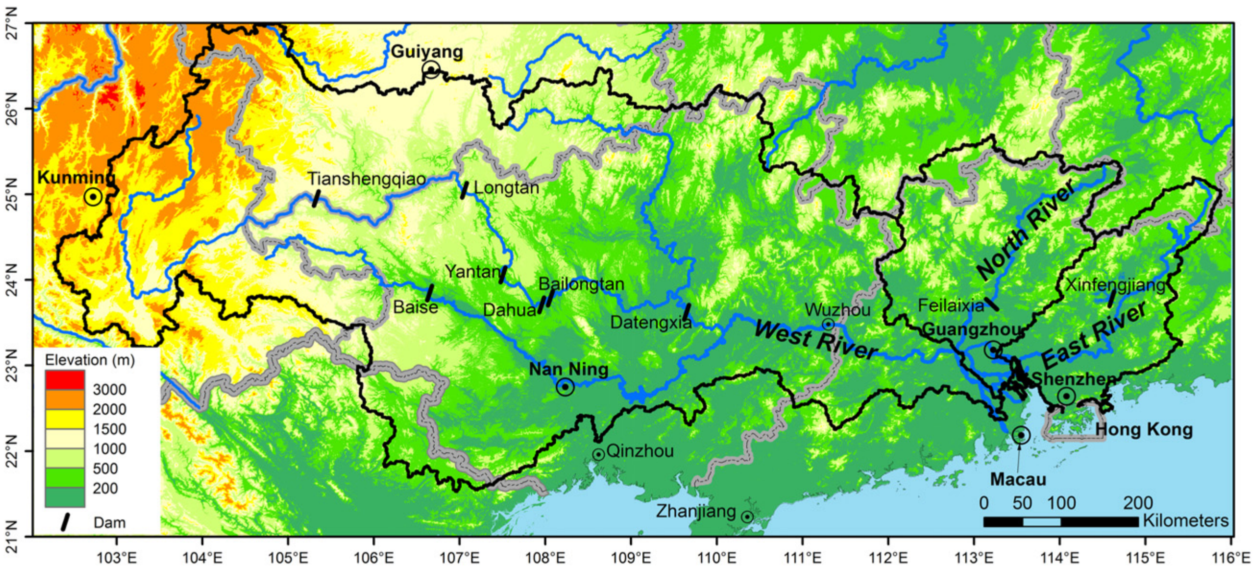

Figure 11 Pearl River basin and major dams.

northeast China and a wetter northwest China would further increase under the IPCC A1B scenario (Nakićenović and Swart 2000).

The future river runoffs and water resources in mainland China have also been studied by using projected precipitation changes (Piao et al. 2010; Meehl et al. 2007; Shen 2010). Due to the large uncertainties involved in projected precipitation, no firm conclusions can be given (Meehl et al. 2007). However, it has been suggested that in general, by the end of 2100, the river runoff would be increased over mainland China (Zhang et al. 2007a) by 7.5% under the IPCC B1 scenario, and by 9.7% under the A1 scenario (Nakićenović and Swart 2000). Annual runoff in the Yellow River basin is projected to increase by 11% (Zhang et al. 2007b) in IPCC A2 scenario (Nakićenović and Swart 2000) and by 5% in the IPCC B2 scenario (Nakićenović and Swart 2000). However, these results are dependent on the accuracy of global climate projections, and Gao et al. (2008) suggested that an accurate high-resolution climate model for mainland China is one of the necessary requirements for skillful future climate projections.

5.13.5 Tackling the Water Resource Problems

In the following subsections, three examples are introduced—the South-to-North Water Diversion project, the Three Georges project, and the practices for managing the Pearl River water resources—to illustrate some measures that have been implemented in order to deal with water resource problems in mainland China.

5.13.5.1 South-to-North Water Diversion Project

The spatial distribution of China's water resources is extremely uneven. The sum of water resources in the Yellow River and the Hai River is less than 6% of the nation's total water resources, but they need to supply water for approximately 40% of the total irrigation land. Moreover, since the late 1970s, northern China has experienced rapid urbanization and economic development; to meet urban and industrial demands for water, groundwater in the region has been overexploited. Land subsidence and regional sandstorms have caused serious environmental problems due to the excessive usage of water resources, and the water shortage is extremely serious in northern China. The Yangtze River generates more than 80% of the nation's total runoff, but its irrigation land area is approximately 30% of the nation's total. To resolve the uneven spatial distribution of water resources, the largest water diversion project in mainland China, namely the South-to-North Water Diversion Project (see Figure 9), has been planned and implemented.

The project is expected to be completed by 2050, and eventually 44.8 billion m^3 of water will be diverted to the north region from the Yangtze River basin annually. This large water diversion project will integrate the water resources in the four river basins, which are the Yangtze River, the Yellow River, the Huai River, and the Hai River. The project consists of three water transferring routes—the Eastern, Middle, and Western Routes—which divert 14.8 billion $m^3 year^{-1}$, 13.0 billion $m^3 year^{-1}$, and 17.0 billion $m^3 year^{-1}$ of water to the north, respectively. These three routes are briefly described in the following sections.

5.13.5.1.1 Eastern Route

Construction of the Eastern Route started in December 2002, and the route is expected to be completed by 2030. The Eastern Route is 1155 km long and diverts water from the downstream Yangtze River via the ancient Beijing-Hangzhou Grand Canal. It is the longest canal in the world and the oldest parts were constructed in the fifth century BCE (Before the Common Era). The main purpose of the canal was to transport grain and other commodities to the Huang River, Huai River, and Hai River plains (in Jiangsu, Anhui, and Shandong provinces), to Tianjin, and finally to Beijing. This route has 23 pumping stations, 9 km of tunnels, and 634 m of siphon sections (Water Technology

2011). A total of 7.67 billion m^3 year^{-1} of water will be used to irrigate croplands, and 6.66 billion m^3 year^{-1} of water will be used to supply the domestic and industrial sectors.

5.13.5.1.2 Middle Route

The Middle Route is 1267 km long, and its construction started in December 2003. This route is expected to be fully completed by 2030. In this route, water is diverted from the Danjiangkou reservoir on the Han River, which is a tributary of the Yangtze River, via canals near the west edge of the Huang, Huai, and Hai plains to Beijing and Tianjin municipalities through Henan and Hebei provinces. The route is regarded as an optimal solution to mitigate the water resource shortage in northern China. The advantages of the route lie mainly in the good water quality and gravitational force used to drive water from the south to north. The diverted water will benefit the people living in an area of 0.16 million km^2, which is mainly composed of the Tangbaihe plain and the middle-western Huang-Huai-Hai plains, and 17 large- and medium-size cities, including Beijing, Tianjin, Shijiazhuang, and Zhengzhou.

5.13.5.1.3 Western Route

The Western Route plans to divert water from the upstream reaches of the Yangtze River to the upper reaches of the Yellow River by a 100-km tunnel through the Bayan Har Mountains. The water diverted by the route will benefit about 0.2 million km^2 of irrigated farmlands and the route will provide 9.0 billion m^3 year^{-1} of water for the domestic and industrial sectors. The main advantages of the route are that it can promote the economic development of some relatively less developed regions in northwest China and improve the environment of the Loess Plateau in North China. Nevertheless, due to the difficulties of constructing such a long tunnel and the ongoing dispute about water resources for the upstream areas of both the Yangtze River and Yellow River, the route is still in the planning stages (Sohu 2011).

5.13.5.2 Three Gorges Project (TGP)

The major task of this project is to construct the Three Gorges Dam (TGD). TGD is located in the Yiling District of Yichang City, in Hubei province, and is the largest water project along the Yangtze River (see Figure 10). Construction of TGD started on 14 December 1994, and the dam was completed on 20 May 2006. Mainly, there are four goals to the project. They are to reduce the flood risks in the midstream Yangtze River, to supply water to the midstream and downstream areas of the river, to produce clean energy, and to improve the Yangtze River's navigation condition from Wuhan to Chongqing (see Figure 10).

According to the design, all of the 26 turbines (with 700 MW generating capacity each) were installed and operating by 2009. There are six extra underground turbines, each with 700 MW generating capacity; three of these turbines were installed and functioning by 2011, with the remaining ones to be completed by 2012. With two other turbines of 50 MW as backup power units, the hydropower station of TGD dam has a capacity of 22 500 MW, which is currently the world's largest hydropower station to produce clean energy.

Flooding is a major problem for the midstream and downstream areas of the Yangtze River, where there are agricultural production bases, millions of people, and important cities such as Wuhan, Nanjing, and Shanghai. TGD can effectively control or minimize floods by using the flood storage capacity of 22 km^3 of the Three Gorges Reservoir (TGR). On 20 July 2010, there was a peak flow of 70 000 m^3 s^{-1} into the TGR, and the reservoir water level rose about 3 m within 24 h; after the TGD regulation, the reservoir outflow was reduced to 40 000 m^3 s^{-1}, which would not cause flooding downstream the reservoir. The benefit from flood control of the TGR in 2010 was estimated at more than 20 billion RMB Yuan (about US$ 2.93 billion in 2010 equivalent).

The reservoir's operational water level during the dry season is 175 m (above the sea level). On 26 October 2010, this water level was reached for the first time after TGR tried to impound water for reaching 175 m in 2008 and 2009. Accordingly, its target of 84.7 TW hour (TWh) of annual power generation was achieved in 2010. By 16 August 2011, the hydropower plant of TGP had generated 500 TWh of electricity since the first operation of a hydropower generator in 2003. In addition, with the improvement of the navigation condition of the Yangtze River reach from Yichang to Chongqing due to the TGR, the maximum freight capacity of a ship has increased from 3000 tons before the project to 10 000 tons after the project. On 25 December 2011, a historical high was achieved in which an annual total of 100 million tons of cargo was transported through the TGD ship locks.

Nevertheless, there are some negative impacts associated with TGP. For example, some archaeological and cultural sites have been submerged by TGR, and 1.3 million people have been relocated. The river ecosystem would have been influenced by regulating natural flow, and the rising and falling of water levels in the range of 145 and 175 m annually has resulted in some geological natural hazards (e.g., landslides). The impoundment of the TGR may impact the downstream lake levels and associated ecosystems, particularly Dongting and Poyang Lakes (Fan 2011). The scouring of riverbeds by water released from TGR is also a negative effect. Moreover, it has been argued that a massive reservoir like TGR might affect the climate systems and trigger more extreme weather and climate events (Wu et al. 2006; Gleick 2008). However, research has confirmed that TGR may influence the weather of the regions only to approximately 10 km away from the reservoir (Zhang et al. 2004).

5.13.5.3 Water Resource Management in the Pearl River

Figure 11 shows the geographic location of the Pearl River basin. Along with the rapid socioeconomic development of the Pearl River delta since the late 1970s, the water demand from the region has dramatically increased and various water problems (e.g., water shortages during droughts, water pollution, and seawater intrusion) have appeared (Cui et al. 2007; Niu and Chen 2010; Wang 2010). To deal with these problems and other issues in the basin, the Pearl River Water Resources Commission (PRWRC) has implemented a series of measures.

5.13.5.3.1 Water Allocation Framework

The water allocation framework established by the PRWRC aims to protect the upstream water sources, to regulate the midstream development, and to harness the downstream environment (Cui et al. 2007; Wang 2010). The aims of water protection in the upstream are to maintain the water quality, to prevent soil erosion, to recover the polluted lakes, to protect ecological systems, and to enhance the construction of small- to middle-scale water conservancy projects. Water regulation in the midstream area is achieved by the construction of a series of water regulation projects and by increasing the capability of allocating water for maintaining navigation and achieving an ecology-required minimum flow during extreme dry periods. For example, through the National Headquarters on Flood Control and Drought Relief, the PRWRC implemented the release of water from a series of the reservoirs, most of them located in the midstream area, for preventing seawater intrusion in the estuarine areas in early 2005 (Cui et al. 2007). Water harnessing in the downstream area aims to enhance the prevention and treatment of the water pollution, to build a water-saving and pollution-preventing society, to handle the outlet salinity problem, and to conduct optimization projects for the water resource allocation.

5.13.5.3.2 Key Water Projects

The existing key water projects in the Pearl River basin include the Feilaixia, Bailongtan, Baise, Dahua, Yantan, Longtan reservoirs and the Tianshengqiao hydro projects (see Figure 11). A project currently being planned is the Datengxia Dam, which will be a key regulation project to safeguard water supply for Macau city and the Pearl River delta. Regional water diversion projects include the Zhanjiang and Qinzhou projects, and the Xijiang and Hongling projects along with a scheme to divert water to the middle of Guizhou province.

Key water-saving projects currently being undertaken include the Mengkaige Irrigation Area and the Youjiang Irrigation Area water-saving projects. Irrigation and drinking water projects are mainly constructed in Yunnan and Guizhou provinces for agricultural irrigation and water supply, and they include the Rundian and Ziqian projects. A special campaign called the Projects with Five Smalls has been launched; these projects include construction of small water pools, small vaults, small dykes, small channels, and small pumps for the effective storing and transferring of water.

5.13.5.3.3 Future Water Demand

By 2030, the projected total water demand over the Pearl River basin in a normal year is 93.9 billion m^3 $year^{-1}$, which is 6 billion more than current demand (Wang 2010). The projected agricultural supply is 56% (53 billion m^3), industry demand is 30% (27.7 billion m^3), and domestic water is 14% (13.2 billion m^3), while the basic flow for in-stream use is 130.3 billion m^3. Urban water use is 37.6 billion m^3, which is 15.8 billion m^3 more than the current demand and approximately 40% of the total protected water use in 2030.

5.13.6 Concluding Remarks

Population growth is the dominant factor of threatening the security of water resources. Since 1979, the one-child policy has been implemented in mainland China. It was estimated that by 2007 China prevented about 400 million births (Anonymous 2011). The efforts to control population growth have undoubtedly mitigated the severity of water shortage. However, the various water resource problems mentioned above are still serious, especially given the prediction of a projected population peak of 1.5 billion around 2033.

The strategies and measures for tackling the vulnerability of water resources in mainland China (Wang 2010) include changing from supply-oriented water management to demand-oriented management and establishing a water-saving society by adjusting the economic structure and industrial layout. The water resource management authorities are carrying out the strictest water management system and increasing the utilization of other water resources, such as reclaimed water and seawater desalinization. Also, the water resource commissions for the river basins are improving the water regulation, promoting rational water allocation, building necessary water infrastructures, strengthening their water regulation capabilities, promoting the use of information-based technology applications, and strengthening integrated water management.

The current situation of water resources and their management in mainland China are not able to meet the increase in demand of water-related usages, such as water supply, protection of the water environment, and prevention of water-related natural hazards, due to population growth, the need to produce food, and the rapid economic development since the late 1970s. Regarding this, Central Document No. 1 in 2011 (Central Committee and State Council 2011), entitled "The Decision on Accelerating the Reform and Development of Water Conservancy," was issued on 29 January 2011. This document is the first comprehensive policy document on integrated water resource management released by the Central Committee and State Council of mainland China. Water resource management, as the first priority among national infrastructure construction, will be pushed forward by both the central government and local governments.

The main tasks identified in Central Document No. 1 include five parts (Central Committee and State Council 2011). Firstly, the water conservancy construction in rural regions and other vulnerable water-related natural hazard areas will be strengthened. Secondly, the harnessing of large rivers and lakes, water resource allocation, and water and soil conservation will be accelerated in a sound manner. Thirdly, significant financial allocation to water projects will be made. Funds for water resources management projects will be raised from multiple channels, and it is expected that a total of 4 trillion RMB Yuan (about US$ 0.6 trillion in 2011 equivalent) will be invested into the water projects for the next 10 years (i.e., up to 2020). Fourthly, the strict management of water resource usage will be enforced, which sets restriction standards for the control of water resource development and utilization, the control of water use efficiency, and the pollution load in water use zones. Fifthly, innovation of the water management system and mechanism will be continuously carried out. It is expected that by 2020 a comprehensive flood control and drought mitigation system in mainland China will be established and urban flood prevention and flood control capacity will have been greatly improved. The total water use for the whole country by 2020 will be limited to 670 billion m^3 $year^{-1}$, and the effective utilization coefficient of irrigation water will reach 0.55.

The possibility of the frequent and sudden occurrence of extreme weather events could increase due to climate change, and new water-related problems are raised in conjunction with the growth of population and the fast development of China's economy. Despite the many challenges in water resource management, including the frequent floods, droughts, and deterioration of the water environment, China has made great efforts in flood control, drought relief, and environmental protection in recent years. Both structural and nonstructural measures have been implemented, which include establishing an institutional framework, improving structural facilities, developing emergency plans, strengthening flood forecasting and warnings, issuing laws and regulations, and enhancing emergency management.

5.14.1 Introduction

In many mountainous regions of the world the accumulation of snow during winter constitutes the main (and sometimes the only) source of streamflow during subsequent warmer months and throughout the year. The dramatic changes in topography within short distances in mountain ranges usually force air masses to release their moisture as they ascend and move across the highest peaks and intermontane valleys. With freezing temperatures, this precipitation usually occurs as snow, and this water can accumulate and remain frozen until warmer conditions start the seasonal, gradual melting of the snowpack that feeds many creeks and rivers in high-elevation regions. This capacity of mountainous areas to accumulate and store water as snow and ice during winter and subsequently release it as meltwater during warmer months, when it is most needed by human populations in adjacent areas, has been recognized and valued by ancient and modern societies in many parts of the world. In recent decades, the importance of mountains as storage and sources of water has been reaffirmed through numerous studies, and the expression 'water towers of the world' has been coined to reflect the crucial significance of these elevated regions to the population and environments in different continents (Viviroli et al. 2009, 2011). However, despite the well-known and generally undisputed importance of mountains as primary sources of freshwater, the number of detailed assessments of the main hydrologic patterns and the factors affecting mountain climate conditions remains limited in many regions. In such cases, the vulnerability of local human populations to water shortages has not been assessed through a comprehensive hydroclimatologic and socioeconomic approach that could help identify, for example, those social and economic sectors more vulnerable to extended droughts, or minimum water levels required for 'normal' operation of local societies.

This chapter provides an overview of recent empirical analyses of snowpack and streamflow records from the Andes between 30 and 37° S (Figure 1), which allow an assessment of the importance of the winter snow on regional river discharges and the identification of their main temporal and spatial patterns over the past 100 years. The relationships between mountain snowpack records and various large-scale ocean–atmospheric variables (such as sea-surface temperatures and the El Niño–Southern Oscillation, ENSO) are also assessed in an attempt to identify the main factors modulating snowpack variations in the Andes. Two complementaries, recently developed Andean snowpack reconstructions covering the past two to eight centuries, are subsequently examined and their main intra- to multidecadal (IMD) patterns identified using time series analysis techniques. Besides the more obvious application in local water management and regional development strategies, this information allows testing the relative significance of the patterns of snowpack observed during the instrumental period in a long-term context. This information may also be relevant for measuring the strength and time stability of the relationships between Andean snowpack and ENSO or other ocean–atmosphere features over most of the past millennium. Finally, the authors comment on the varying vulnerabilities to water shortages in the basin of Río Mendoza (one of the main rivers in central-western Argentina, Figure 1) and the potential benefits of integrating instrumental and reconstructed hydrologic data together with results from climate and climate-driven hydrological models into local socioeconomic assessments, water management practices, and adaptation planning.

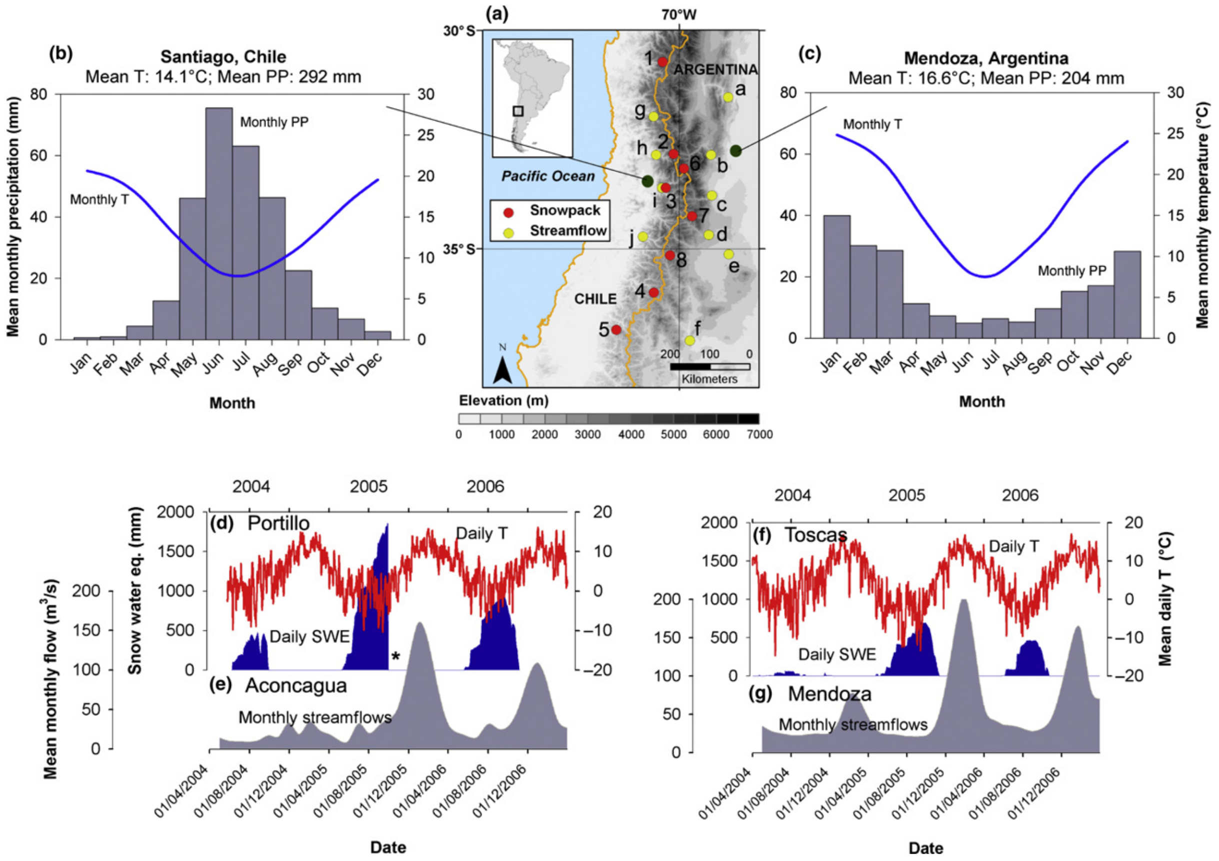

Figure 1 (a) Location of the stations with the longest and most complete snowpack and streamflow records (red and yellow dots, respectively) in the Andes of Chile and Argentina between 30 and 37° S. For station metadata see **Table 1**. (b, c) Climographs showing the climatic regimes characteristic of the cities of Santiago, Chile, and Mendoza, Argentina, on the western and eastern lowlands adjacent to the Andes. To facilitate the comparison of these diagrams, mean monthly precipitation (left *y*-axes) and temperature (right *y*-axes) are depicted using the same scale. The units for the precipitation axes are indicated in (b) and the temperature axes are labeled on the far right in (c). Note the different climatic regimes between these sites with a marked peak in precipitation during the austral winter (summer) for Santiago (Mendoza). (d) Mean daily temperatures (red line) and snow water equivalent (blue area) recorded at Portillo, Chile (station 2 in (a)) between 1 April 2004 and 31 March 2007. These years were selected because they provide a good indication of the range of conditions existing in the high arid Andes: the winter of 2004 was extremely dry, that of 2005 was extremely snowy, and that of 2006 was slightly above 'normal.' An asterisk (*) indicates partial lack of data for the 2005 snow season. (e) Mean monthly discharges for Río Aconcagua at Chacabuquito (station h in (a), located downstream of Portillo) between April 2004 and March 2007. Note the good correspondence between the amount of snow accumulated in the basin headquarters during winter and the streamflow recorded during the following warmer months. (f) Same as (d) but for the Argentinean station Toscas, on the eastern side of the Andes (station 6 in (a)). (g) Same as (e) but for Río Mendoza at Guido, downstream from Toscas (station b in (a)). The left axes in (d)–(g) are labeled on the far left and the right axes are labeled on the far right, and the data for Portillo–Aconcagua are depicted in the same scale as those for Toscas–Mendoza to facilitate the analysis of similarities and differences on both sides of the Andes.

5.14.2 Andean Snowpack Is a Crucial Water Resource in Vast Semiarid Areas of Southern South America

The portion of the Andes between 30 and 37° S in southern South America (Figure 1(a)) has a mean elevation of about 3500 m, with several peaks reaching over 6000 m. The weakening and northward displacement of the subtropical Pacific anticyclone during the austral winter enhances the westerly flow across central Chile, producing a marked cold season peak of precipitation in the lowlands and over the mountains to the east (Miller 1976; Aceituno 1988; Falvey and Garreaud 2007; Figure 1(b)). Owing to the high elevation and north–south orientation of the cordillera, most of the moisture from the Pacific air masses is released in the mountains and little Pacific moisture reaches the easternmost slopes of the Andes in Argentina. The semiarid region east of the cordillera experiences a continental regime with a marked warm season precipitation peak associated with moist air masses from the northeast as well as convective processes (Prohaska 1976; Figure 1(c)).

Several heavily populated cities (including Santiago de Chile, the nation's capital city, and the city of Mendoza, in central-western Argentina) and extensive agricultural areas are located in the lowlands flanking the Andes at these latitudes. Human activities in these productive regions are almost entirely dependent on the systematic use of mountain meltwater for human consumption, industries, irrigation, hydroelectric generation, and aquifer recharge. Collectively, over 10 million people live in these regions (INDEC 2001; INE 2003) and enjoy the socioeconomic, recreational, and environmental benefits provided by this natural resource. The dependence on Andean freshwater is even more evident along the eastern, drier Argentinean foothills and plains, which receive on average only 200 mm of precipitation per year (**Figure 1(c)**). The development of complex irrigation systems has allowed the existence of oases that stand out as islands of green amid vast oceans of dry lands, forming a territorial pattern common to human settlements across central-western Argentina. For example, in the Province of Mendoza oases represent only 3% of the total surface but contain about 98% of the population and concentrate a large share of the more dynamic socioeconomic activities. Given these particular environmental and socioeconomic conditions, water scarcity is not just a hydroclimatic phenomenon in this region. These Latin American drylands have been characterized as 'hydraulic societies' (Worster 1985), as social tissues are strongly associated with intensive use of water resources that historically have been adapted to 'control' a hostile natural environment. While the space becomes territory through water allocation, water appropriation and use gives rise to and reproduces a scheme of social and political relationships in which quotas of power are distributed. Although water deficits are structural, water shortage scenarios threaten local economies and anticipate increases in the frequency and intensity of social, political, and economical conflicts (Montaña 2008). In this context, efforts to bridge knowledge derived from natural and social sciences may provide very interesting perspectives, as better knowledge of the relative magnitude and temporal extension of past droughts (and their potential behavior in the future) constitutes a valuable resource to anticipate future vulnerabilities and develop adaptation strategies toward resilience.

As in many regions with snowmelt-dominated hydrologic regimes, in the Andes of central Chile and central-western Argentina there is a well-known, strong, direct relationship between winter snow accumulation and spring–summer river discharges (see, e.g., **Figure 1(d)–1(g)**). Local water agencies in Chile and Argentina are well aware of this relationship and have implemented a network of measuring stations that regularly monitor the accumulation of snow during the winter at several high-elevation sites. The snowpack information (which for some sites spans over five decades of continuous records) is routinely used to produce warm season and annual water supply forecasts for the main river basins on both sides of the Andes. Interestingly, however, besides these short-term forecasting products, very few analyses of instrumental snowpack variations are available for this portion of the Andes, and the main spatiotemporal patterns in these mountain snow records are only starting to be understood.

Major rivers in this region have also been monitored for several decades using a relatively small but well-maintained network of gauging stations. Some of the mean monthly streamflow records available for these rivers cover almost the entire twentieth century and are of excellent quality. This is a rarity for Andean South America, which generally lacks long, good-quality hydroclimatic data. There are also records from other smaller rivers and creeks that generally span for a few decades but in some cases contain periods with missing information. However, despite the existence of these valuable records and the well-known, crucial socioeconomic importance of mountain meltwater, the number of studies assessing the main patterns of IMD variations in river discharges is limited (see later).

5.14.3 Andean Snowpack and Streamflow Records Share a Strong Regional Common Signal

Masiokas et al. (2006) presented the first attempt to integrate snowpack records from Chilean and Argentinean stations and provided a comprehensive assessment of maximum winter snow accumulation data over the 1951–2005 period. Their results generally agreed with previous climatic and hydrometeorological studies showing a marked Pacific, ENSO-related influence on precipitation in this area (e.g., Rutlland and Fuenzalida 1991; Compagnucci and Vargas 1998; Escobar and Aceituno 1998; Montecinos and Aceituno 2003). However, their analyses provided further insight into the main temporal and spatial patterns in the snowpack records and their relationships with local climate, ENSO events, and large-scale atmospheric variables. Masiokas et al. (2006) also quantified the relationship between winter snow records and river discharges in the region and evaluated possible causes for the observed streamflow and glacier trends over the second half of the twentieth century.

Masiokas et al. (2006) showed that, despite the very low number of snowpack records existing in the Chilean and Argentinean sides of the Andes between 30 and 37° S, these records share a high percentage of common variance at interannual and longer timescales. These analyses were based on maximum winter snow water equivalent values (MSWE) as a surrogate for total snow accumulation at each site and a regional record developed from the six stations with the longest and most complete records. This dataset has subsequently been expanded and updated (e.g., Masiokas et al. 2010, 2012; **Figure 2**), although the number of stations remains small compared to other regions such as western North America or the European Alps (**Figure 2(a) and 2(b)**; **Table 1**). Collectively, these records currently cover different portions of the 1951–2010 period, and despite the large latitudinal range of the stations the mean correlation coefficient from all possible paired combinations is 0.683. These individual snowpack records show a strong year-to-year variability ranging from 0% to over 400% of their long-term mean, and the snowiest and the driest winters are concurrently captured in most records throughout the region (**Figure 2(a)**).

Examination of streamflow records shows even stronger similarities than the snowpack records (**Figure 2(b)**; Masiokas et al. 2010). The stronger streamflow similarities probably relate to the overall lower quality or regional representativeness of the snowpack data plus the different inherent characteristics of snowpack and streamflow interannual variations in this region. However, when the individual records are aggregated into regional averages, the similarities between the MSWE and the streamflow series are remarkable, with a very strong time-stable common signal at interannual and interdecadal timescales (**Figure 2(c)**). This result is not surprising given the predominant role of snowmelt in the river discharges of this region. It is interesting to note, however, that the first

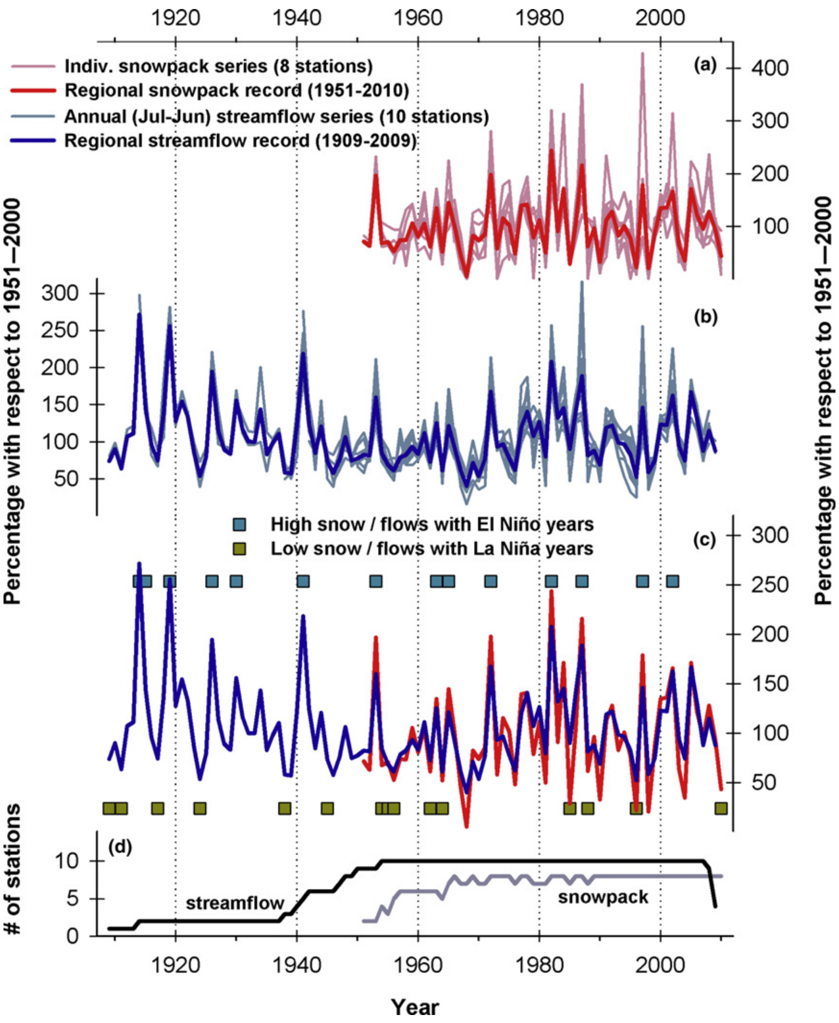

Figure 2 (a) Winter maximum snow water equivalent records (pink lines) for the eight snowpack stations shown in Figure 1(a). The 1951–2010 variance-adjusted regional snowpack average is shown with a red line. (b) Jul.–Jun. mean annual series (light blue lines) of the 10 streamflow stations in Figure 1(a), together with a regionally averaged river discharge record (blue line). (c) Comparison of the regional records of winter snowpack and mean annual streamflow (red and blue lines, respectively) shown in (a) and (b). The Nov.–Feb. river discharge record (not shown) portrays virtually identical features to the annualized data. El Niño years (Giese and Ray 2011; light blue boxes) generally coincide with above-average hydrologic measurements in the Andes. La Niña years (ochre boxes) usually reflect an opposite pattern – dry years in the Andes – but there are notable exceptions such as the extremely dry winters of 1968, 1998, and 2004, which did not coincide with La Niña events in the tropical Pacific. (d) Number of stations used to compute the regional snowpack and streamflow records in any given year. All series in (a)–(c) are expressed as percentages with respect to the 1951–2000 common period mean, but note the different scales used in each case.

integrative, quantitative analyses using data that cover the past several decades and from the eastern and western slopes were not performed until very recently (Masiokas et al. 2006, 2010).

As expected from a snowmelt-dominated regime, the late spring–early summer months (Nov.–Feb.; which account for almost 60% of the annual total flows) show the highest correlations with the snowpack record (Masiokas et al. 2006). The correlation between the MSWE record and the regionally averaged mean annual streamflows is almost high ($r = 0.922$, Figure 2(c)). These results clearly reflect the crucial influence of mountain snowpack on freshwater availability in the adjacent lowland areas in Chile and Argentina and suggest that, at a regional scale, *c.*85% of the streamflow variance observed over the past six decades could be explained by the snowpack record alone (Figure 2(c)). This also suggests that despite the low number of stations used in these analyses, the simple regional series depicted in Figure 2(c) can be considered relatively reliable indicators of the main interannual and interdecadal (IMD) hydrologic variations that occurred in this portion of the Andes approximately during the past 100 years.

As in many other mountainous areas of the world, in the Andes of central Chile and central-western Argentina the glaciers and periglacial features such as rock glaciers constitute important water resources and may contribute with significant amounts of meltwater to the surface runoff of a certain basin. The hydrological significance of the existing ice masses in this arid region becomes particularly important during extremely dry years when little or no solid precipitation occurs at the upper watersheds. Unfortunately, very few systematic, local assessments are available to properly evaluate the relative

Table 1 Snowpack and streamflow records used in this study

Variable	*Station*	*Latitude, longitude*	*Elevation (m)*	*Period*	*Average*	*Data source*
Snowpack	1–Quebrada Larga	30°43′ S, 70°22′ W	3500	1956–2010	222 mm	DGA
	2–Portillo	32°50′ S, 70°07′ W	3000	1951–2010	637 mm	DGA
	3–Laguna Negra	33°40′ S, 70°08′ W	2768	1965–2010	584 mm	DGA
	4–Lo Aguirre	36°00′ S, 70°34′ W	2000	1954–2010	943 mm	DGA
	5–Volcán Chillán	36°50′ S, 71°25′ W	2400	1966–2004	800 mm	DGA
	6–Toscas	33°10′ S, 69°53′ W	3000	1951–2010	295 mm	DGI
	7–Laguna del Diamante	34°15′ S, 69°42′ W	3310	1956–2010	453 mm	DGI
	8–Valle Hermoso	35°09′ S, 70°12′ W	2275	1952–2010	784 mm	DGI
Streamflow (river)	a–Km. 47.3 (San Juan)	31°32′ S, 68°53′ W	945	1909–2008	65.2 $m^3\ s^{-1}$	SSRH
	b–Guido (Mendoza)	32°51′ S, 69°16′ W	1550	1909–2009	48.9 $m^3\ s^{-1}$	SSRH
	c–Valle de Uco (Tunuyán)	33°47′ S, 69°15′ W	1200	1954–2009	28.6 $m^3\ s^{-1}$	SSRH
	d–La Jaula (Diamante)	34°40′ S, 69°19′ W	1500	1938–2009	30.9 $m^3\ s^{-1}$	SSRH
	e–La Angostura (Atuel)	35°06′ S, 68°52′ W	1200	1906–2009	35.2 $m^3\ s^{-1}$	SSRH
	f–Buta Ranquil (Colorado)	37°05′ S, 69°44′ W	850	1940–2009	148.3 $m^3\ s^{-1}$	SSRH
	g–Cuncumén (Choapa)	31°58′ S, 70°35′ W	955	1941–2010	9.6 $m^3\ s^{-1}$	DGA
	h–Chacabuquito (Aconcagua)	32°51′ S, 70°31′ W	1030	1913–2010	33.0 $m^3\ s^{-1}$	DGA
	i–El Manzano (Maipo)	33°36′ S, 70°23′ W	890	1946–2010	107.8 $m^3\ s^{-1}$	DGA
	j–Bajo Los Briones (Tinguiririca)	34°43′ S, 70°49′ W	518	1942–2010	50.7 $m^3\ s^{-1}$	DGA

The codes used in **Figure 1** are indicated together with the stations' names. The long-term average values at each site are expressed as millimeters of water equivalent for snowpack data and cubic meters per second for mean annual (Jul.–Jun.) streamflow records. DGA, Dirección General de Aguas, Santiago, Chile (www.dga.cl); DGI, Departamento General de Irrigación, Mendoza, Argentina (www.irrigacion.gov.ar); SSRH, Subsecretaría de Recursos Hídricos, Buenos Aires, Argentina (www.hidricos.gov.ar). See Masiokas et al. (2006, 2012) for more details. Masiokas, M. H., R. Villalba, D. A. Christie, et al., 2012: Snowpack variations since AD 1150 in the Andes of Chile and Argentina (30°–37° S) inferred from rainfall, tree-ring and documentary records. *J. Geophys. Res.*, **117**, D05112, doi: 10.1029/2011JD016748.

contribution of glaciers vs. snow in a particular site at a given year (Milana 1998; Favier et al. 2009). It should be noted, however, that the hydrological contribution from glaciers is highly variable depending on the size and the glaciated area of the basin. For small basins with a large proportion of their area covered by glaciers and ice-rich periglacial features, the contribution from these ice masses is obviously very important, but as the area of the basin becomes larger, snowmelt becomes the main factor regulating streamflow and the contribution from glaciers is usually of secondary importance. The streamflow records shown in Figure 2(b) come from sites where the proportion between glaciated vs. nonglaciated area is relatively small and snowmelt is therefore the predominant factor modulating surface runoff.

Masiokas et al. (2010) extended the analyses they performed in 2006 and focused on the main IMD variations in snowpack and streamflow records using individual station data and regionally averaged series. They found that, except for three gauging stations that showed statistically significant, positive changes, linear trends in most snowpack and streamflow records are nonsignificant over the past 60–100 years of record. However, several important IMD features were identified embedded in these linear trends. These low-frequency features were more consistent and easier to identify in the streamflow series than in the snowpack data. As discussed earlier, this is probably due to the relative shortness and overall lower quality of the snowpack records, together with the more variable nature of snow accumulation at the selected locations.

The regional streamflow average depicted in Figure 2(c) was improved and updated from Masiokas et al. (2010) but essentially shows the same IMD patterns as discussed in our earlier study. In this regional series (and to a lesser extent in the individual river data, see Masiokas et al. 2010), two significant changes in mean conditions or regime shifts mark the transition between three well-defined periods (Figure 5(a)). The period between 1909 and 1944 can be characterized by wetter than normal conditions with a noticeable peak in 1914–1922. A significant drop in regionally averaged discharge flows can be observed between 1945 and 1976. This interval contains the highest concentration of extreme low flows: 4 of the 10 driest years on record occurred between 1954 and 1971 (Figure 5(a)). Conditions shifted again to above-average levels in 1977, and the 1977–1987 period is, on a regional basis, the overall 'wettest' period on record when compared to all other moving windows of 5–20 years in length between 1909 and 2009. After the extreme wet period ending 1987, the regionally averaged values dropped gradually and have fluctuated around the long-term average until recent times (Figure 5(a)). Analyses of the relative significance of all moving time windows of 5–20 years in length (Masiokas et al. 2010; Mauget 2011) indicate that despite the occurrence of some dry years after 1987, the average conditions of the past two decades cannot be considered statistically different from the long-term mean of the regional series. As expected, results for the warm season (Nov.–Feb.) regional series were extremely similar to those obtained for the annualized record (results not shown).

Other studies that have also assessed the temporal variability of streamflow records on this portion of the Andes have mostly focused on single-station records (rather than regional averages) and have generally assessed linear trends of mean monthly, seasonal, or annual series (e.g., Carril et al. 1997; Pellicciotti et al. 2007). Their results differ depending on the period or season of analysis and between river basins, but in general there is an overall agreement with the results discussed earlier, with most stations showing nonsignificant or marginally significant linear trends and with the period between the 1940s and the mid-1970s standing out as the driest interval for most sites (e.g., Carril et al. 1997). In contrast, Pellicciotti et al. (2007) report significant decreasing trends in 1970–2004 streamflows recorded at the upper section of the Río Aconcagua basin (upstream from station h in **Figure 1**). Other more recent analyses have provided complementary results regarding spatial and temporal patterns of variability and changes in the hydrological regimes of rivers flowing from the western Andean slopes in south-central Chile. Rubio-Álvarez and McPhee (2010) used seasonal and annual streamflow records from 44 rivers between 34 and 45° S and identified two main subregions with distinctive patterns of variability located north and south of the 37.5° S parallel. Annual streamflows in the northern subregion (which overlaps with the region of interest of this chapter, see **Figure 1**) showed a significant 10-year cycle, but no conclusive linear trends were found in this series or in the seasonal averages. Previous studies (Menegazzo and Radicella 1982; Compagnucci and Araneo 2005) based on streamflow records from the eastern (Argentinean) slopes have found that at these latitudes the rivers share a large percentage of common variance and could be considered relatively homogeneous over the instrumental period.

Cortés et al. (2011) analyzed the streamflow distribution throughout the year along the Chilean slopes of the Andes between 30 and 40° S. They found that the hydrological regimes of rivers north of 35° S were mostly dominated by snowmelt, whereas rivers further south (where the Andes have a lower elevation and the conditions are wetter, with rainfall distributed more evenly throughout the year) gradually shifted toward rain-dominated regimes. Analyses of the date marking the timing of the center of mass of annual flows for each water year (CT; Stewart et al. 2005) between 1961 and 2006 revealed no CT changes for almost all snowfed watersheds (14 of 15) in the northern sector, and a consistent pattern of streamflow timing toward earlier in the year (i.e., toward winter) in 22 of 25 rivers south of 35° S (Cortés et al. 2011). The fact that no changes in CT have occurred in the north despite the documented warming at high-elevation sites is interesting and contrasts with the results obtained in similar climatic regions in the Northern Hemisphere, where significant changes toward earlier streamflow timing associated with warmer temperatures have been reported for snow-dominated basins (Stewart et al. 2005; Fritze et al. 2011). Cortés et al. (2011) suggest that this situation is due to the overdominant role of precipitation on the hydrologic regimes of these snowfed basins, in which the effect of rising temperatures could be largely overridden by variability related to precipitation.

Indeed, other studies (see, e.g., Masiokas et al. 2006, 2012) have also found that variations in the regional snowpack and streamflow records are very closely linked to variations in winter and annual total rainfall in central Chile. These similarities are to be expected given the relatively simple nature of the hydrological system of this region, which is primarily driven by moisture coming from the Pacific in a succession of westerly frontal systems concentrated during the winter months (Falvey and Garreaud 2007). This situation alleviates to some extent the problem of constructing long, representative hydroclimatic time series, as it allows the use of a relatively limited number of station records to capture the main hydrologic patterns in this region. Moreover, this offers the possibility of inferring or validating the information provided by one variable (e.g., snowpack) using data from other remaining variables (e.g., central Chile rainfall and/or Andean streamflows). Masiokas et al. (2012) further propose that it is possible to use different precipitation proxies to extend back in time the information on snowpack variations in the Andes (see discussion of their results later).

5.14.4 Relationship of Local Hydroclimatic Variations with Large-Scale Atmospheric Features such as ENSO and PDO

The significant influence that tropical Pacific Ocean–atmospheric conditions exert on the study region's hydroclimatic variability has been known for decades. In their pioneering study of the 'Southern Oscillation,' Walker and Bliss (1932) include rainfall variations in central Chile and pressure changes in Santiago among the variables used to calculate the Southern Oscillation Index (SOI) for the austral winter. Many subsequent studies have assessed the relationship between ENSO and central Chile rainfall variations (e.g., Pittock 1980; Quinn and Neal 1983; Aceituno 1988; Rutlland and Fuenzalida 1991; Montecinos et al. 2000; Montecinos and Aceituno 2003; Quintana 2004). Additional analyses have also examined the influence of ENSO on Andean snow accumulation (Escobar and Aceituno 1998; Masiokas et al. 2006, 2010) and mountain river discharges (Waylen and Caviedes 1990; Caviedes 1998; Compagnucci and Vargas 1998; Norte et al. 1998; Waylen et al. 2000; Compagnucci et al. 2000; Rubio-Álvarz and McPhee 2010; Gimenez et al. 2010; Cortés et al. 2011). Most of these studies concur that El Niño events are generally associated with wetter-than-normal conditions in the study region, whereas during La Niña years drier conditions are more likely to occur. Cortés et al. (2011) found that CT time series of Chilean rivers in snow-dominated basins were indeed strongly correlated to various ENSO indices, with the annual streamflow center of mass occurring later (i.e., toward the summer) during El Niño years because of the excess in precipitation during the cold season. In addition, various analyses of historical ENSO variations (Quinn and Neal 1983; Ortlieb 1994, 2000) have relied on the warm/wet relationship between ENSO and precipitation levels in central Chile to identify and estimate the severity of El Niño years between the sixteenth and nineteenth centuries.

Masiokas et al. (2006) quantified the association between tropical Pacific ocean–atmosphere conditions and Andean snowpack variations using seasonally averaged 2.5°×2.5° gridded sea surface temperatures (SST) and sea level pressure (SLP) time series derived from the National Centers for Environmental Prediction–National Center for Atmospheric Research (NCEP–NCAR) reanalysis global database (Kalnay et al. 1996). **Figure 4** portrays the correlation between the regional MSWE series and Jun.–Sep. (midwinter) SST and SLP averages as reported by Masiokas et al. (2006). Together with results from earlier seasons (not shown) these correlation maps indicate that the strongest associations are concentrated during the winter months and mostly over the tropical Pacific domain. This interesting finding was corroborated with multiple regression analyses in which several large-scale, seasonally averaged climatic indices such as the Niño 3.4 index, the SOI, the Pacific Decadal Oscillation (PDO), the Antarctic Oscillation (AAO), and two indices indicative of Atlantic conditions were

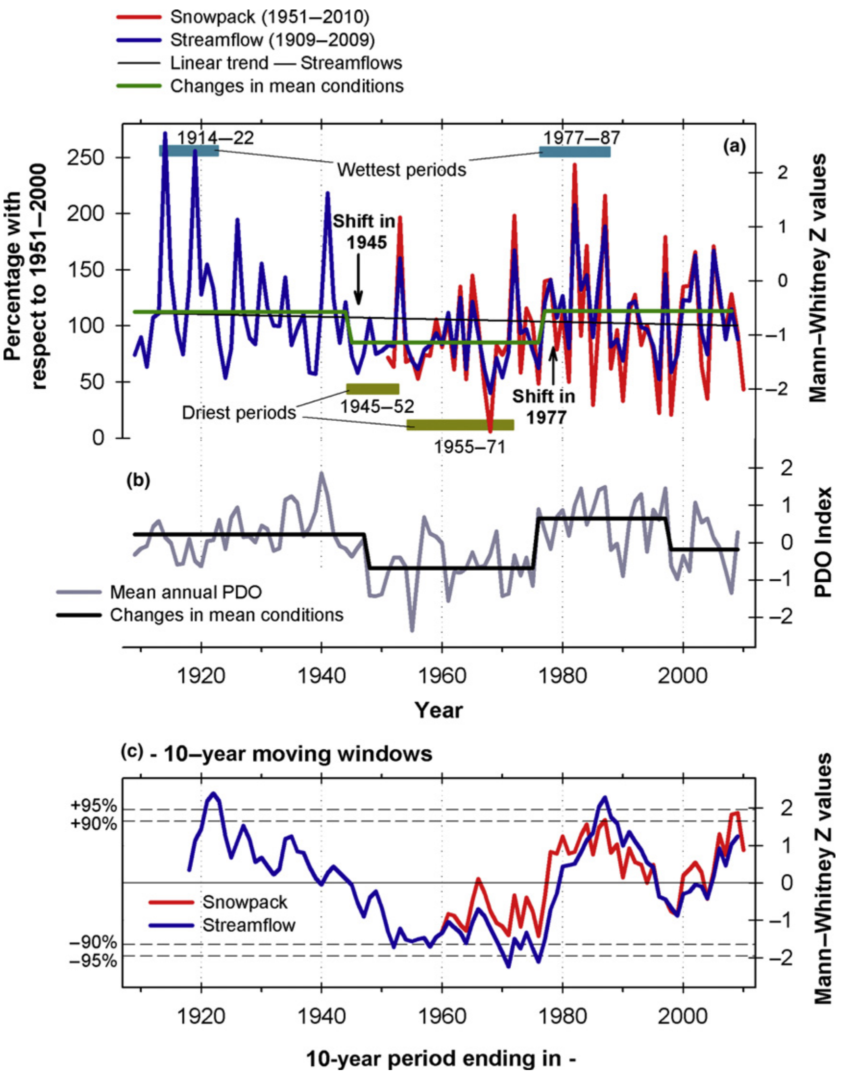

Figure 3 (a) Regional snowpack and streamflow records (red and blue lines, respectively) for the Andes of central Chile and central-western Argentina (**Figures 1 and 2**, data updated to 2009–2010 from those presented in Masiokas et al. 2010). Given the strong similarities between these records, only the temporal patterns of the longer streamflow series are shown in this figure. The least squares linear trend in regional river discharges is slightly negative but nonsignificant over the 1909–2009 interval. Regime shifts in mean flow conditions (green line) were calculated based on Rodionov (2004, 2006; refer to these references for details on this technique). Two statistically significant regime shifts were identified in 1945, when mean levels dropped 32%, and in 1977, when they increased 29%. The driest and wettest periods on record (i.e., those periods with the highest concentration of extreme high and low values in the record) are indicated by horizontal bars. These extreme intervals were determined from all possible nonoverlapping moving windows of 6–20 years in length using nonparametric Mann–Whitney tests and Monte Carlo simulations as described in Mauget (2003, 2004, 2011). Essentially this method samples data rankings over running time windows, converts those samples to Mann–Whitney *U* statistics, and then normalizes the *U* statistics to Z statistics using Monte Carlo generated null parameters. Based on the magnitude of the Mann–Whitney Z values this algorithm can identify time windows containing significant incidences of low or high data rankings. This is an objective, relatively simple, and statistically based way of detecting the driest and wettest intervals in these hydrological time series. (b) Mean values for 1909–2009 Jul.–Jun. of the PDO index (gray line) and shifts in mean regime levels (black line) identified in this series using Rodionov's technique. (c) Running 10-year samples of Mann–Whitney *Z* values as determined using Mauget's technique. Horizontal dashed lines indicate the 90 and 95% positive and negative significance determined from Monte Carlo simulations. Note the similar patterns of decadal-scale variations between the regional streamflow and snowpack records.

used as potential predictors of winter snowpack in the Andes (see Masiokas et al. (2006) for more details). The multivariate regression trials revealed that none of the seasonal values of these climatic indices for the Nov.–Apr. (early summer–late fall) period was significantly correlated with the snowpack record, and, therefore, they cannot be used as predictors of snow accumulation during winter in the Andes. In contrast, significant correlations were found between the snowpack record and the May–Jul. (early–midwinter) averages of the Niño 3.4, SOI, and the AAO indices. However, owing to intercorrelation among these variables only the SOI was included in a final regression model, which was able to explain about 44% of the variance in the snowpack record. Overall, these results present an important limitation for the prediction of winter snow accumulation using data from these large-scale climatic indices from the preceding months. Given the

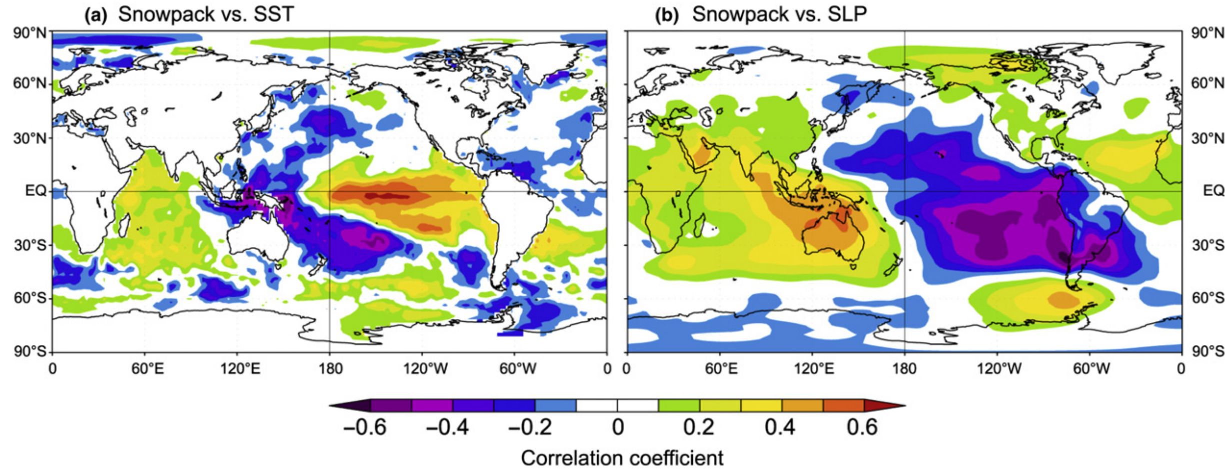

Figure 4 Correlation maps showing the varying spatial association between the regional snowpack series and seasonally averaged NCEP–NCAR reanalysis 2.5° × 2.5° sea surface temperature (a) and sea level pressure (b) gridded data over the 1952–2003 interval. The maps were created using the linear correlation and mapping routines available at the website of the Earth System Research Laboratory, Physical sciences Division, NOAA [Available online at http://www.esrl.noaa.gov/psd/data/correlation/]. Note that (a) shows the well-known ENSO-like wedge pattern over the tropical and subtropical Pacific (e.g., Trenberth and Caron 2000; Trenberth et al. 2002). Strong positive correlations occur over the Niño 3 and Niño 4 regions, and negative correlations are mostly concentrated over the subtropical western Pacific Ocean. The pattern in (b) also shows a noticeable ENSO-related structure (Trenberth and Caron 2000). Figure modified from Masiokas, M. H., R. Villalba, B. H. Luckman, C. Le Quesne, and J. C. Aravena, 2006: Snowpack variations in the central Andes of Argentina and Chile, 1951–2005: large-scale atmospheric influences and implications for water resources in the region. *J. Clim.*, **19**, 6334–6352.

socioeconomic importance of the Andean snowpack, improved predictive skills are desirable and more research is needed to identify better predictors of snowpack records from atmospheric variables or climatic indices from the period prior to the austral winter (e.g., McCabe and Dettinger 2002). Since the most serious challenges in managing the mountain water supply will likely occur during below-average snowfall years, special attention should also be paid to those large-scale atmospheric linkages associated with (or leading to) extreme dry years in the Andes. Masiokas et al. (2006) proposed the development of predictor series based on a north–south index utilizing SLP or geopotential height data from the subtropical Pacific off the coast of central Chile combined with those from the Amundsen–Bellingshausen Seas (Am–Be) in the southeast Pacific (Figure 4(b)). Blocking activity in the Am–Be area is strongly associated not only with ENSO variability (Renwick 1998) but also with snowpack high and low values in the Andes (see later). A better understanding of additional atmospheric teleconnections affecting conditions in the southeast Pacific (e.g., Jacobs and Comiso 1997; Marques and Rao 1999) may lead to improved predictive skills for estimating winter snowpack conditions in this region. Some studies have reported results that provide promising perspectives to tackle this issue. Berri and Flamenco (1999) found strong correlations between October and March streamflows of Río Diamante (station d in Figure 1) and the previous Mar.–Apr. and concurrent Nov.–Dec. Niño 3 SSTs and used this relationship to develop a multiple linear regression model of warm season surface runoff in this basin. More recently, Gimenez et al. (2010) used the winter values of the Multivariate ENSO Index (MEI) and snowpack data to predict Río San Juan streamflows (station a in Figure 1) at a 6-month lead time.

Enhanced blocking activity over the Am–Be area in the southeast Pacific is a known ENSO-related atmospheric teleconnection occurring during El Niño events (Karoly 1989; Renwick 1998; Kiladis and Mo 1998). In 1991, Rutlland and Fuenzalida and subsequently Montecinos and Aceituno (2003) reported that this enhanced blocking activity was closely related to above-average winter rainfall totals in central Chile. Masiokas et al. (2006) investigated the influence of these tropospheric circulation anomalies on Andean snowpack variations using peak winter (Jun.–Sep.) mean 500-hPa geopotential heights derived from the gridded NCEP-NCAR reanalysis dataset of Kalnay et al. (1996). For the 10 snowiest years Masiokas et al. (2006) found extensive and well-defined regions of averaged positive height anomalies (associated with enhanced blocking activity) concentrated between 60–70° S and 90–120° W in the Am–Be area and a concurrent weakening of the subtropical Pacific anticyclone around 30 and 40° S and 130 and 150° W (Figure 5(a)). Interestingly, the 10 driest years on record corresponded with an almost exactly opposite anomaly pattern, with negative winter 500-hPa geopotential height anomalies over the Am–Be region and positive anomalies in the subtropical South Pacific between 25 and 40° S (Figure 5(b)). These results confirmed the findings of previous studies (e.g., Rutlland and Fuenzalida 1991) and indicate that large-scale tropospheric circulation anomalies in the mid to high latitudes of the Southern Hemisphere are indeed a very important forcing that modulates snowfall in the Andes. Based on the maps in Figure 5, it seems reasonable that an increase in the number of blocking events in the Am–Be area and a weakening of the subtropical Pacific anticyclone during winter result in a northward migration of the westerly storm tracks, and above-average precipitation totals in the study area. The remarkably similar height anomaly pattern of opposite sign for the driest years (Figure 5(b)) suggests that a stronger Pacific anticyclone and depleted height anomalies in the SE Pacific during winter determine a southward displacement of westerly

Figure 5 (a) Jun.–Sep. mean 500-hPa geopotential height anomalies for the 10 snowiest years in the central Andes as identified by Masiokas et al. (2006) for the period 1951–2005. Mean monthly gridded data were obtained from the NCEP/NCAR reanalysis global dataset (Kalnay et al. 1996). Contours are in meters with a 5-m contour interval, and zero lines are omitted. Positive (negative) contour anomalies are shown as solid (dashed) lines. (b) Same as (a), but for the 10 driest years in the central Andes. The maps were created as follows: for each event year and grid point, mean peak winter (Jun.–Sep.) height anomalies from the 1968–1996 reference period were calculated from monthly data and subsequently averaged to create separate composite 500-hPa height anomaly maps for the 10 snowiest and driest years on record. Figure slightly modified from Masiokas, M. H., R. Villalba, B. H. Luckman, C. Le Quesne, and J. C. Aravena, 2006: Snowpack variations in the central Andes of Argentina and Chile, 1951–2005: large-scale atmospheric influences and implications for water resources in the region. *J. Clim.*, **19**, 6334–6352.

air masses with the resulting reduction in snowfall in the Andes (Masiokas et al. 2006).

As mentioned earlier, Masiokas et al. (2010) focused on the main IMD patterns in the snowpack and streamflow records. They found that the inception of the driest period of the twentieth century in this portion of the Andes was roughly coincident with a shift toward extended negative conditions in the PDO in the mid-1940s (e.g., Mantua et al. 1997; Mantua and Hare 2002; **Figure 3(a) and 3(b)**). The shift toward wetter conditions in 1977 in the Andes also corresponds with a very well-known regime shift toward more positive PDO levels in 1976–1977. Despite some discrepancies between the regional streamflow record and the PDO (especially noticeable on a year-to-year basis, **Figure 3(a) and 3(b)**) the occurrence of these relatively synchronous regime shifts in the 1940s and 1970s led Masiokas et al. (2010) to suggest that the slowly evolving patterns of the PDO may have influenced the IMD hydrologic behavior at these latitudes in the Andes. The correspondence observed between the extended ‘cool’ PDO levels between 1944 and 1976 and the below-average winter snowpacks and annual discharges recorded during this interval (**Figure 3**) resembles the relationship between cool ENSO events and dry conditions in the Andes discussed in the literature. Likewise, the wetter hydroclimatic conditions recorded in the Andes after 1977, concurrent with a ‘warm’ phase of the PDO, also resemble the warm–wet relationship discussed above in relation to the impacts of ENSO in this portion of the Andes (see, e.g., Rutlland and Fuenzalida 1991; Masiokas et al. 2006). Dettinger et al. (2000) found a similar, consistent pattern of positive correlations between streamflow data from the study area and interannual and decadal ENSO-like climatic variations across the Pacific. However, whether these cool–dry/warm–wet relationships are entirely valid at the longer timescales characteristic of the PDO remains uncertain, and further research is needed to clarify this interesting issue.

5.14.5 Reconstructing Andean Snowpack Variations from Multiple Proxies

Masiokas et al. (2012) developed two complementary reconstructions of Andean snow accumulation covering the past two to eight centuries. The evidence used to develop and validate these snowpack reconstructions includes instrumental rainfall

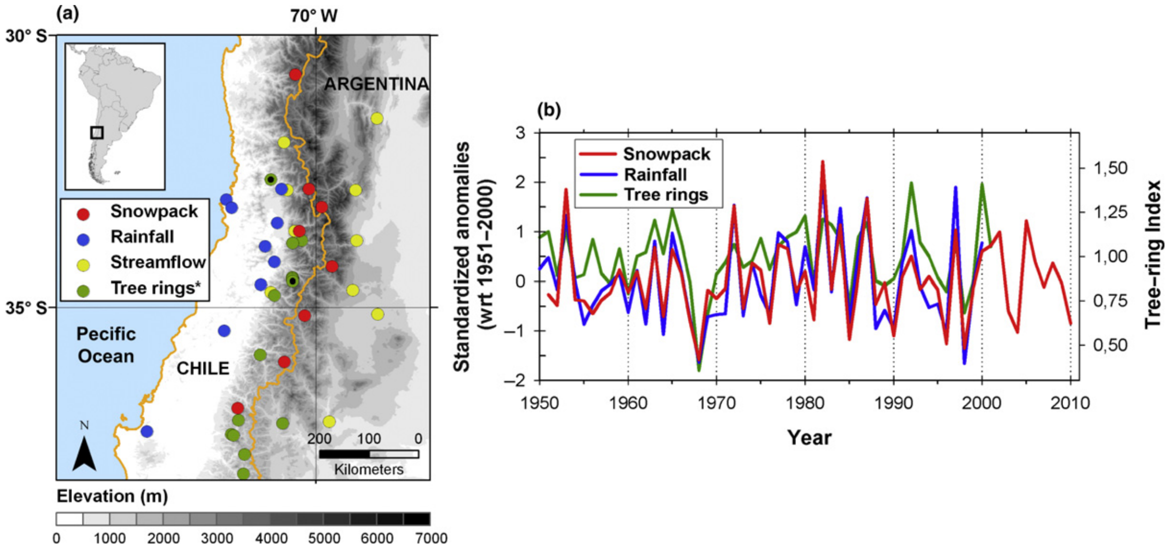

Figure 6 (a) Location of snowpack, rainfall, streamflow, and tree-ring sites used in the reconstruction of snowpack as described in Masiokas et al. (2012). Note (*): from the available network of tree-ring sites (green dots), the two tree-ring chronologies finally selected in the reconstruction model are marked with a black dot. (b) Comparison of the regional records of Andean snowpack and winter rainfall in central Chile, and the mean tree-ring index of the two selected chronologies as mentioned earlier. The resemblance between the snowpack and rainfall series is remarkable. The tree-ring series from these precipitation-sensitive trees also shows strong similarities with the instrumental records. The figure shows the 1951–2010 period covered by the snowpack series, but the regional central Chile rainfall series covers the period AD 1866–2000 and the tree-ring series goes back to AD 1150. The snowpack and rainfall series are expressed as standardized anomalies from the 1951–2000 period, whereas the tree-ring series is adimensional. See text for more details. Figure modified from Masiokas, M. H., R. Villalba, D. A. Christie, et al., 2012: Snowpack variations since AD 1150 in the Andes of Chile and Argentina (30°–37° S) inferred from rainfall, tree-ring and documentary records. *J. Geophys. Res.*, **117**, D05112, doi: 10.1029/2011JD016748.

and streamflow data from adjacent lowlands, a variety of documentary records, and century-long tree-ring series of precipitation-sensitive species from the western side of the Andes. All these records share a common regional hydroclimatic signal (**Figures 2 and 6**) largely because of this region's particular and relatively simple hydroclimatic regime, with the moisture mainly coming from winter frontal systems of Pacific origin. Masiokas et al. (2012) argue that these different hydroclimate records can be used as snowpack 'proxies' for the development and independent validation of reliable snowpack reconstructions covering periods prior to 1951 when instrumental snowpack data are first available. Rainfall data from central Chile (very strongly correlated with snow accumulation values in the adjacent mountains) were used to extend the regional 1951–2010 snowpack record back to AD 1866. Subsequently, snow accumulation variations since AD 1150 were inferred from precipitation-sensitive tree-ring width series. The reconstructed snowpack values were validated with independent historical and instrumental information, including (1) documentary accounts of snow conditions over the main Andean pass between 1760 and 1890 (Prieto et al. 1999a), (2) newspaper-based records of snow depth along the main Andean pass between AD 1885 and 1996 (Prieto et al. 2000, 2001), (3) documentary accounts of the discharge of the Mendoza river (and other rivers) in the Argentinean piedmont between 1600 and 1960 (Prieto et al. 1999b), (4) the compilation of evidence for wet years in central Chile used by Ortlieb (1994) to infer the severity of El Niño events between AD 1535 and 1900, and (5) a record of total monthly hours of rain in the city of Santiago de Chile for the period 1824–1850 (Taulis 1934). Masiokas et al. (2012) assumed that the duration of the rainfall events during winter is very likely positively correlated with the amount of precipitation received in the lowlands of central Chile and in the adjacent mountains to the east. Thus, extended periods of rain in Santiago during the winters of 1824–1850 should correspond with higher-than-normal snow accumulations in the Andes, and vice versa.

According to Masiokas et al. (2012), the verification tests performed on the snowpack reconstructions offer some confidence in the reliability of these reconstructed time series. However, the authors indicate that because of the varying nature of the proxy data available, the resulting reconstructions contain certain characteristics that can be considered as either strengths or limitations depending on the needs of the end users of these data. For example, the first reconstruction approach, based on central Chile rainfall data, showed exceptional skill for modeling Andean snowpack variations (84% of variance accounted for by the model over the 1951–2000 calibration period; Masiokas et al. 2012). However, this reconstruction was restricted to the period after AD 1866 by the length of the instrumental records (**Figure 7**). The high quality of this first reconstruction could be very useful, however, for local water resource managers, decision makers, and stakeholders interested in long, highly reliable mountain snowpack data as a basis for infrastructure planning and for developing a better understanding of Andean hydroclimatic variability over the past 150 years. In contrast, the tree-ring based reconstruction model was less accurate in modeling the instrumental snowpack record over the calibration period (45% explained variance and higher associated uncertainties than the other model; (Masiokas et al. 2012)). Nevertheless, the resulting reconstruction offers the unique possibility of assessing in

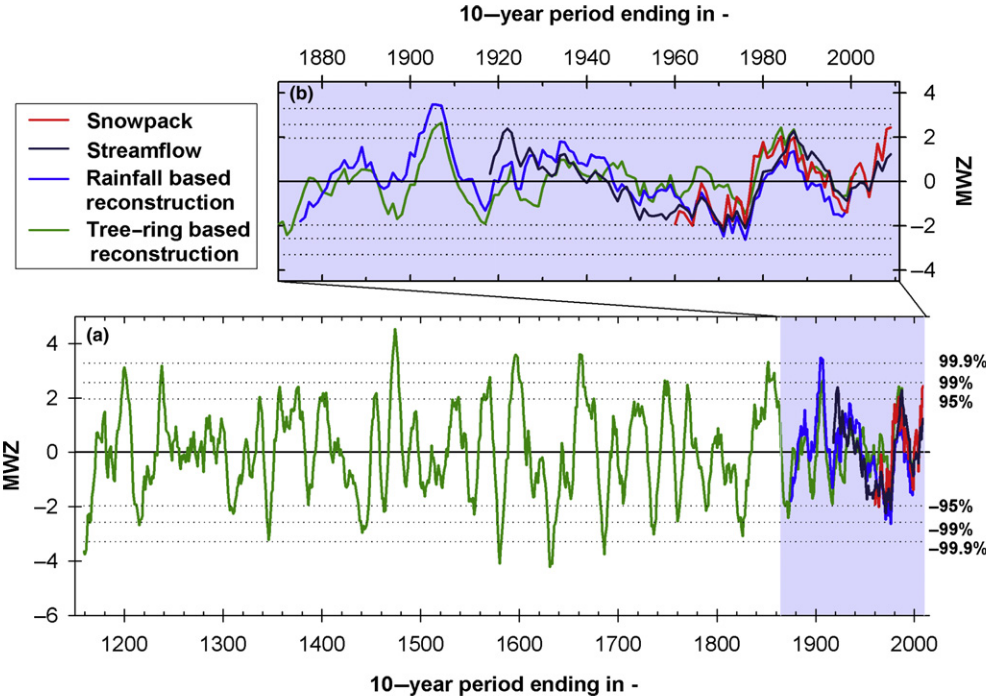

Figure 7 Comparison of the decadal patterns of variations in instrumental snowpack and streamflow records (red and dark blue lines, respectively), with those of the rainfall-based and tree ring-based snowpack reconstructions (blue and green lines, respectively) recently developed by Masiokas et al. (2012). As in **Figure 5(c)**, here, Mann–Whitney Z statistics for running 10-year samples of each original series are shown. (a) Period covered by the tree ring-based reconstruction (AD 1150–2001). (b) Period since AD 1866 covered by the rainfall-based reconstruction. Horizontal dotted lines indicate positive and negative significance at the 95, 99, and 99.9% confidence levels derived from Monte Carlo simulations. In this case, 10-year windows reaching these levels would be considered statistically wetter or drier than expected under essentially stationary conditions (see Mauget 2011 for details on the methodology). Note the overall similarities of decadal variations between the instrumental and reconstructed series. Reproduced from Masiokas, M. H., R. Villalba, D. A. Christie, et al., 2012: Snowpack variations since AD 1150 in the Andes of Chile and Argentina (30°–37° S) inferred from rainfall, tree-ring and documentary records. *J. Geophys. Res.*, **117**, D05112, doi: 10.1029/2011JD016748.

a quantitative and objective manner the history of snowpack fluctuations over the past 850 years in this Andean region (Figure 7). This reconstruction represents the first annually resolved mountain snowpack reconstruction covering most of the past millennium in the Southern Hemisphere. According to Masiokas et al. (2012), the lower skill of the tree ring-based model is very likely due to the differential tree-growth response to extreme dry vs. extreme wet or snowy conditions: as with other precipitation-sensitive tree-ring species, the chronologies usually reflect the dry to extreme dry conditions better than extreme wet years for which the soil moisture content exceeds the physiological needs of the trees (Fritts 1976).

Masiokas et al. (2012) used the same approach used in 2010 for assessing the main IMD modes of variability in the snowpack reconstructions. This technique had already been used in other instrumental hydroclimatic records (Mauget 2011) but is novel in paleoclimatic studies. The approach offers very promising perspectives for identifying the most extreme intervals in a given time series while testing their statistical significance in a simple and objective manner. The timing and significance of the intervals with the highest and lowest values detected by the running MWZ method (Mauget 2011) for each window length were recorded and tested collectively to identify the driest and snowiest periods in the reconstructed time series. The results provide a very useful reference for assessing the relative significance of recent conditions in a long-term context, and can also be used to evaluate the extent and magnitude of historic droughts and snowy periods in this region. Figure 7 shows that in general the instrumental and reconstructed time series show broad similarities using a 10-year period as a reference. This was somewhat expected in the rainfall-based reconstruction, but the similarities with the tree ring-based reconstruction are interesting and suggest that despite the inherent limitation of this reconstruction in capturing extreme high snowpack values (see earlier discussion), the overall decadal-scale regional patterns of snowpack variations are still represented relatively accurately in this time series. This information could be useful for both local water resource managers and ongoing modeling analyses intended to predict decadal climate patterns (Meehl et al. 2009; Keenlyside and Ba 2010), which are of more direct relevance to society than the more distant, highly uncertain centennial-scale climate projections generally discussed in the literature. However, it should be noted that only those models that accurately simulate (hindcast) the statistics and the inherent variability observed on the instrumental hydroclimatic records and on the most relevant atmospheric and ocean circulation features will provide a solid basis for the assessment of future vulnerabilities and the development of adaptive strategies to increase resilience.

These main temporal patterns identified in the reconstructions can also provide relevant, quantitative information for larger scale studies involving the main factors affecting the hydroclimate in this portion of the Andes. Besides the well-known influence of ENSO in this region, recent analyses have also identified a potential influence of the PDO on the low-frequency modes of variability in the snowpack and streamflow records of this region (Masiokas et al. 2010; see also Dettinger et al. 2001). The long Andean snowpack reconstructions presented by Masiokas et al. (2012) allow an assessment of the strength and time stability of the relationships with ENSO and the PDO over most of the past millennium and may complement the great number of studies (e.g., Stahle et al. 1998; Cobb et al. 2003; MacDonald and Case 2005; D'Arrigo et al. 2005; D'Arrigo and Wilson 2006; Gergis and Fowler 2009) that discuss the regional manifestations and long-term variability of these large-scale ocean–atmosphere features.

5.14.6 Climate and Hydrological Sciences Informing Vulnerability Reduction and Adaptation

The term 'vulnerability' can be defined as the degree to which a system, such as a rural community or agricultural producer, is susceptible to the adverse effects of stressors and change (Smit and Wandel 2006). Given the exposure of a community or agricultural producer to climatic hazards and their impacts, vulnerability results from an equation involving the sensitivity the degree to which a system is affected by climate-related stimuli and the adaptive capacity the ability of a system to adjust to climatic risks and opportunities by increasing its coping range. Both sensitivity and adaptation are related to variables such as natural, human, social and institutional capital, economic resources, and infrastructure. Climate exposures articulate with others from economic and social spheres, composing double exposures (Leichenko and O'Brien 2008). Vulnerabilities are also unequally distributed in space and in relation to different social groups or actors. They could come not only from these exposures but also from undesired effects of adaptive practices, as one's adaptation practices may cause increasing vulnerabilities in others (Montaña 2011).

The Río Mendoza basin is a very interesting case study because it expresses well the different vulnerabilities to sustained water deficits. Although all agricultural producers are vulnerable to droughts, the degree to which these producers will be affected by this natural phenomenon will depend on their productive system. For example, producers of crops that are relatively resistant to water stress, such as vine growers, are inherently less vulnerable to water deficits than horticulture producers, which are entirely dependent on a certain watering frequency. Likewise, large-scale capitalized producers from both vine and horticultural productive systems, who have access to high technology irrigation systems and who are able to drill wells and pump groundwater according to their needs, are obviously less vulnerable to fluctuations in surface runoff from mountain rivers than the smaller scale producers whose subsistence is entirely dependent on water distributed through surface irrigation. There are also double exposures, as the vulnerability of the smaller producers has already been increased by previous exposure to the dominant globalized agribusiness, in a vicious circle of increasing sensitivity to droughts and decreasing capacities to adapt to this phenomenon. Likewise, vulnerability to droughts depends on location. Producers located upstream or near the sources of water tend to be less sensitive to droughts than those located downstream from urban centers or at the far end of the irrigation network. The more favorable locations are accessible only to producers with enough capital to acquire these more expensive oases lands or to those able to start new farms in the natural dry shrublands along the Andean piedmonts that require significant investments in land cleaning, leveling, well construction, pressurized irrigation systems, etc.

Extreme hydroclimatic events such as extended droughts will only consolidate or accelerate the existing tendency toward a spatial and socioeconomic segregation of the agricultural producers of the oases in central-western Argentina, widening the gap between the dominant players of the local agri business and those who are barely able to survive as subsistence producers. In many cases, these small-scale producers will have to neglect their farms to work on a salary basis for large-scale companies or even be forced out from the agricultural sector and migrate to cities, where they will join the growing number of urban poor. Scenarios of increasing water deficits suggest an intensification of the current process of transformation of the socioeconomic and agricultural structure of these hydraulic societies along the eastern side of the Andes (Montaña, 2011).

Interestingly, the degree of vulnerability of the different players in this hydraulic society may change considerably based on specific adaptive practices. The flows of Río Mendoza have been recently regulated to reduce seasonal and interannual variability in the river discharge and to compensate for spring and autumn water deficits in crops. As several studies have projected an earlier onset of spring snowmelt in response to potentially future warmer conditions in high-elevation regions, this may result in reduced vulnerabilities to potential changes in the seasonal supply of water, ultimately producing only minor impacts on the local agricultural system. However, given the spatial distribution of agricultural lands and the less favorable, scattered location of goat breeders in the drylands downstream from the main users of the Río Mendoza waters, all positive effects that regulation provides to the agricultural oasis will work against the delivery of flows to the distal part of the basin. As these regulations do not ensure ecological flows, a more intense and regulated use of water upstream by the social groups with highest power clearly reduces the possibilities of water 'escaping' to the downstream part of the basin where desert communities are settled. This evident inequity constitutes an interesting case in which a particular set of adaptive practices benefit some sectors but considerably increase the vulnerability of other groups. Although their subordinate social position largely determines the sensitivity of these poor rural communities to various economic and environmental factors, extended droughts will ultimately be the trigger for increased conflicts in this hydraulic society.

The recent findings on the spatiotemporal patterns of mountain snowpack and streamflows provide a new perspective for a better understanding of vulnerabilities in these dryland, coupled human and natural systems. In a social research context, these findings offer the possibility of contextualizing contemporary droughts and their socioeconomic impacts in a long-term perspective. For example, the relative magnitude of the 2004–2005 drought, locally perceived as severe, can now be revaluated in the light of the existing snowpack and streamflow time series. This new evidence indicates that such extreme dry years are not as uncommon as initially believed. This may in turn help raise awareness of the possibility that harsher and longer droughts will occur in the future, and encourage appropriate adaptation measures.

A better understanding of the functioning of these coupled natural and social systems, and the possibility of linking the occurrence of dry and wet periods over the past century with the evolution of recent crises in local agricultural economies, may also offer the very interesting opportunity of exploring the balance between 'social' and 'natural' factors involved in these particular crises. This integrative assessment could be approached by focusing on the local economic effects of particularly dry or wet years and the ENSO impacts in this region, or by focusing on longer timescales where intra- to multidecadal dry or wet periods (which appear to be modulated by the PDO, see earlier) may have also affected the evolution of certain favorable or unfavorable economic cycles in these societies.

The existence of long, reliable hydroclimatic time series and strong, time-stable correlations between Andean snowpack and river discharges with central Chile rainfall and Pacific SSTs constitutes a possible early warning tool that may help anticipate the occurrence of droughts in the eastern foothills of the Andes. This information is also crucial for a detailed testing and validation of results from global and regional climate and hydrological models. Only models that accurately simulate (hindcast) the statistics and the inherent variability observed on the hydroclimatic records and on the most relevant atmospheric and ocean circulation features will provide a solid basis for the assessment of future vulnerabilities and the development of adaptive strategies to increase resilience. With these caveats in mind, various measures to rationalize the water resources and accommodate agricultural practices could be taken based on this information. Other strategies involving longer timescales for planning and development of major projects and investments (e.g., major hydraulic infrastructure such as dams) may in turn be decided taking into account robust modeling results and the inherent multidecadal patterns of fluctuations observed in Andean hydroclimatic records. For example, the construction of the Potrerillos dam in the Río Mendoza basin took almost a century from the first proposal of the project. Increased awareness of the recent past, present, and possible future behaviors of the Andean hydroclimatic system could help shorten the decision times and promote cost-effective measures for better management of the water resources. Whether in the case of purely empirical hydrological research or in a comprehensive socioeconomic vulnerability assessment, the mere existence of the long-term Andean snowpack and streamflow data for these river basins constitutes an important step toward reducing the inherent uncertainties associated with climate scenarios currently available from global climate models and opens the possibility of formulating adaptive strategies based on a more site-specific, 'bottom-up' approach.

Acknowledgments

This research was supported by the Argentinean Agency for the Promotion of Science and Technology (grant PICTR02-186), FONDECYT Project 1121106 (Chile), and the CRN2047 Project from the Inter American Institute for Global Change Research (IAI). The last project is supported by the US National Science Foundation (grant GEO-0452325). The US Department of Agriculture (USDA) is an equal opportunity provider and employer. The authors are grateful to Guillermo García Zamora and Departamento General de Irrigación (Mendoza), Subsecretaría de Recursos Hídricos (Buenos Aires), Erich Weidenslaufer, and Fernando Vidal (Dirección General de Aguas, Chile), for providing the snow course and streamflow records used in this study. Richard Branham (IANIGLA-Mendoza) kindly provided assistance with the time series analysis routine used in the chapter. The comments from one anonymous reviewer and the help from the editor, Faisal Hossain, to improve the manuscript are greatly appreciated.

5.15.1 Introduction

Although much of the available information on the European mountain environment relates to the Alps, Europe has a great variety of mountain regions, from Scandinavia to Mt. Etna in Sicily and from the vast Spanish sierras to the densely wooded Carpathians. There is no standard definition of a mountain on the European scale, and national definitions vary considerably. Price et al. (2004) delineated the European mountainous areas by using topographical criteria related to altitude and steepness. According to this methodology, Europe's mountains cover 19% of the continent. The proportions of the mountainous areas vary considerably across the continent: mountains occupy 15% of the area of northern and western Europe and 24% of eastern and southern Europe. A map of the Europe's mountain area based on the above-mentioned criteria is reported in **Figure 1**. The figure clearly reveals the great differences between the high mountains – Alps, Pyrenees, and many other mountains of the Iberian Peninsula, the Romanian Carpathians, southern Bulgaria, and Southern Fennoscandia – and the lower 'middle' mountains that account for a much greater proportion of the total area of the mountains in Europe.

The European Environment Agency (2002) report on the Alpine region recognizes the European mountains as the continent's ecological backbone. Europe's mountains are of vital importance to the continent's population in several ways. These areas are the continent's 'water towers' supplying much of the continent's water, especially in summer, and are sources of hydroelectric power. A comparison between the proportion of discharge that can be expected on the basis of catchment size and the actual discharge measured demonstrates the hydrological significance of the mountainous areas. As an example, with a mean contribution ranging from 26% (Danube) to 53 % (Po) of the total discharge, the Alps supply up to two to six times more water than might be expected on the basis of catchment size alone (Viviroli et al. 2007; Weingartner et al. 2007). They are also centers of diversity, both biological and cultural, and provide opportunities for recreation and tourism, based on natural attributes and cultural heritage.

A large climatic variation, with major north–south and west–east trends, is superimposed to the local climatic variations generated by the topographic gradients. This is accompanied by a great diversity of land covers. These mountainous environments are therefore very diverse at every scale, in terms of climate, ecology, economy, and other characteristics. European mountain landscapes are cultural landscapes reflecting long-term interactions of human beings with biophysical systems.

The extreme environment makes mountain areas prone to natural phenomena such as floods, landslides, rockfalls, and avalanches. Landscapes of high topographic relief and steep slopes favor lifting of the low-level unstable air and initiation of condensation processes (Davolio et al. 2009), orographically enhanced precipitation, and high rates of mass wasting and sediment transport. In this chapter, we will mainly focus on landslides, debris flows, and flash floods as typical natural hazards in European mountain terrain. These processes are often co-occurring because of the common triggering (intense precipitation) and the common favoring circumstances (steep slopes). Intense precipitation may trigger landslides, debris flows, and floods, which in some cases may be associated in the same event. Moreover, the morphology of the mountainous basins with small and steep river catchments can turn the intense runoff generation into severe devastating flash floods and flooding (Gaume et al. 2009). These events may trigger large erosion and sediment transport, and, under appropriate topographic conditions, they lead to the formation of debris flows (Rickenmann et al. 2008) including woody debris (Comiti et al. 2006).

In some cases, similar techniques are also used for the event risk management of these hazards. Precipitation thresholds are used to identify landslide/debris flows inducing precipitation events (Guzzetti et al. 2007). Precipitation thresholds are also used as flash flood diagnostic methods, which aim at assessing

the potential for flash flood at the regional scale, based on the analysis of current soil moisture status (Norbiato et al. 2008).

Landslide/debris flows and flash floods also share elements of vulnerability. For the case of debris flows and flash floods, this is typically represented by dispersed urbanization, transportation, tourism structures, as well as urbanized areas downstream of small basins. In the European terrain areas, alluvial fans represent the morphological category where flash flood/debris flows hazards and vulnerability typically overlap (see Malet et al. (2005) for an example in the French Alps). Indeed, on one hand, streamflow, debris flood, and debris flows are among the main processes contributing to the edification of alluvial fans. On the other hand, alluvial fans are historically favored building sites for human communities. Economic damages and fatalities associated with flash flood and debris flows (Guzzetti 2000; Marchi et al. 2010; Salvati et al. 2010) point to the need for better risk assessment management methodologies.

Despite being a serious natural hazard that affects regions throughout Europe, landslide, debris flows, and flash floods remain a poorly documented natural phenomenon. These events integrate processes and occur at space–time scales that are not usually covered by conventional hydrometeorological monitoring networks. Let us consider for instance the illustrative case of flash floods. The occurrence of extreme events in ungauged watersheds generally means that there is no measured discharge information or formal record of the magnitude of the event. Furthermore, data on previous flash floods are scattered among local authorities where flooding has occurred and various companies and research units that may have unpublished technical reports. These sources of information are often difficult to obtain and are generally in the national language of the country where the flood occurred. Existing inventories of past floods (Herschy 2005; Barredo 2007) include only few data on flash floods that occurred in Europe and lack quantitative information on the meteohydrological and hydraulic characteristics of the events. The lack of centralized national and international databases for storing meteohydrological, hydraulic, and socioeconomic data relating to past flash flood events within Europe hinders the development of understanding of their magnitude and occurrence (Viglione et al. 2010). Therefore, their documentation mainly relies on postevent surveys, which provide the essential, but often fragmented, observational resource (Borga et al. 2008).

Mountain geo- and ecosystems are highly sensitive to climate because of feedbacks associated with high-elevation snow cover, albedo, and heat budgets (Haeberli et al. 2007; Vavrus 2007). Temperature changes in the European Alps, for example, have increased twice as much as the global average since the late nineteenth century, and precipitation and other variables have also changed nonlinearly, with significant regional and seasonal differences, and differences by elevation and aspect (Auer et al. 2007; Haeberli et al. 2007; Brunetti et al. 2009). Changes in temperature and precipitation are considered to have a range of secondary effects, including the retreat of glaciers, the extent and duration of the snow cover, the temperature and distribution of permafrost, and the dynamics of the catchment runoff (including extremes) (Beniston et al. 2003; Vanham et al. 2008). These changes have implications on the susceptibility of triggering of both landslides and flash floods, with major consequences in both mountain areas and downstream.

This chapter provides a set of indications of landslides (see Section 5.15.2) and flash flood (see Section 5.15.3) hazard in mountainous terrains of Europe. A literature review concerning the number of fatalities due to landslide and flash floods in selected European regions complements the description. Finally, Section 5.15.4 reports the discussion and conclusion, with implication for risk management in European mountain areas.

5.15.2 Landslide Hazard in Mountain Terrains of Europe

Landslides represent a major threat to human life, property, buildings, infrastructure, and natural environments in most mountainous and hilly regions of Europe (c.f. SAFELAND 2010). Landslides are defined as the gravitational movement of a mass of rock, earth, or debris down a slope (Cruden 1991), which are basically described by two characteristics: (1) the material involved (*rock*, *rockdebris*, *earth*) and (2) the type of movement (*falls*, *topples*, *slides*, *spreads*, *flows*) (Cruden and Varnes 1996). The above classification, for example, rockfall, debris flow, and earth slide, facilitates the understanding of the failure mechanism. The occurrence and reactivation of landslides are conditioned by a number of contributing factors related to bedrock and soil properties, including slope morphology, relief energy, or land-use cover.

Currently, no comprehensive and up-to-date database of landslide occurrence and impacts exists in Europe. Inventories of landslides exist in most European countries, but access is often made difficult by restrictions and administrative and language barriers. Moreover, criteria used for the compilation differ widely from region to region. In spite of these difficulties, an interesting compilation has been carried out by the European Environment Agency (2010a), which provides an assessment of main landslide events that have occurred over the period 1998–2009 and reports the major landslide phenomena that occurred in Europe during the period 2003–2009. The report was compiled from an analysis of global disaster databases, such as the EM-DAT (2010), NatCatSERVICE (2010), and International Consortium on Landslide (ICL 2010), as well as by review of the scientific literature and the web. It is shown that the different sources of information varied significantly in their representation of the problem.

The distribution of landslide hazards over Europe is strongly linked to the geological and relief conditions of the continent. Owing to these reasons, mountainous areas, such as the Scandinavian Peninsula, the Alps, and the southern part of Europe, are most prone to landslides. Central Europe is only marginally affected, as is eastern Europe with the exception of Romania and Bulgaria (Jelínek et al. 2007; Schweigl and Hervás 2009).

For the period 1998–2009, almost 70 major landslides were recorded in different databases in Europe. These events, which often occurred at multiple sites for the same triggering factor, claimed a total of 312 lives and damaged or destroyed an extensive amount of infrastructure including roads and houses. From the analysis of the data, no obvious trend emerges in terms of landslide impacts. It is noted that potential impacts are often aggravated by land-use management including uncontrolled urbanization.

According to the report by the European Environment Agency (2010a), most catastrophic landslides in Europe are associated with heavy and/or prolonged rainfalls, coupled with soil erosion on mountain slopes (Hervás 2003). It is therefore interesting to analyze the minimum rainfall depths/rates (rainfall thresholds) required to initiate the slope instability in the various European countries. Guzzetti et al. (2007) revised the rainfall thresholds for landslide initiation for the mountainous regions included in the Central European Adriatic Danubian South-Eastern Space (CADSES) area. The work is based on a database of 853 rainfall events that resulted or did not result in landslides in the CADSES area for the period 1841–2002, with the majority of the events in the period 1954–2002. For each event, the collected information includes (1) location of the area affected by the rainfall and landslide event, (2) rainfall conditions that resulted (or did not result) in the slope failure, (3) type and number of the triggered landslides, (4) main rock types cropping out in the region, and (5) climate information. Guzzetti et al. (2007) used the rainfall, landslide, and climate information stored in the archive to identify the rainfall thresholds for the initiation of landslides in the CADSES area (**Figure 2**). In the intensity–duration plot shown in **Figure 2(a)**, rainfall conditions that resulted in landslides (663 events) are shown by filled symbols and rainfall conditions that did not result in slope failure (190 events) are shown with open circles. Despite considerable scattering and clustering at specific durations, a clear trend exists in the data. With increasing rainfall duration, the minimum intensity likely to trigger slope failure decreases linearly in the log–log plot. The self-similar behavior is clear for at least three orders of magnitude of rainfall duration, that is, from less than 20 min to about 12 days. Next, in **Figure 2(b)**, each line shows the probability that a percentage of the known landslide events lies below the line. Finally, a Bayesian approach is used to define the threshold model for likely landslide occurrence and to permit its calibration in a reasonably objective manner, and the results are shown in **Figure 2(c)**. The minimum level of intensity duration required to initiate landslides can be well approximated by the following equation:

$$I = 0.1 + 8.5D^{-0.65} \tag{1}$$

where I indicates the rain rate in millimeters per hour and D indicates the rainfall duration in hours.

Local and regional rainfall thresholds such as those developed by Guzzetti et al. (2007) may be used for operational landslide warning systems, under the assumption that future landslide events are subject to the same controls as past events. This assumption may be challenged if weather patterns change. Changes in temperature and precipitation are considered to have a range of secondary effects, including the retreat of glaciers, the extent and duration of the snow cover, or the distribution of permafrost. However, although there is the possibility of increased mass-movement activity, changes in activity are hardly visible in observational records.

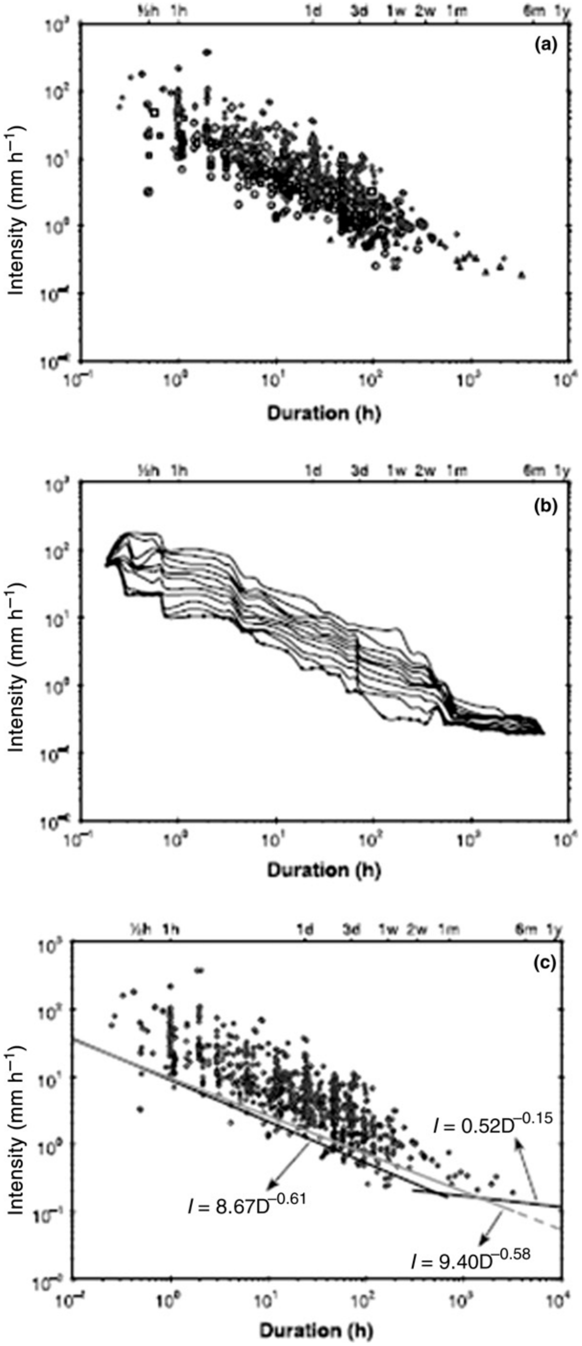

Figure 2 Rainfall intensity–duration thresholds for the initiation of landslides in the CADSES area. Source: From Guzzetti, F., S. Peruccacci, M. Rossi, and C. P. Stark, 2007: Rainfall thresholds for the initiation of landslides in central and southern Europe. *Meteorol. Atmos. Phys.*, **98,** (3–4), 239–267.

In addition to possible changes in temperature and rainfall intensity, changes in sediment supply and land use are important determinants of mass-movement frequency and magnitude. Recent observations at several sites in the Swiss Alps indicate that sediment supply can in fact change significantly as a result of permafrost degradation of rock and scree slopes or mass movements related to other processes. At the same time, with the ongoing and eventually complete downwasting of glaciers, certain sources of sediment may become depleted or disconnected from downslope systems; an increase of vegetation cover at higher altitudes could reduce erosion rates and create more stable conditions in the long term. In this case, conditions might improve and imminent hazards could decrease at certain locations on a multidecadal timescale.

Stoffel et al. (2008) suggest that, provided that sediment supply is not a limiting factor, debris flows have the potential to become larger in the future than they were in the past, but not necessarily more frequent and clearly conditioned by local site conditions (Stoffel et al. 2008; Jomelli et al. 2009; Bollschweiler and Stoffel 2010). Recent developments at high-elevation sites have shown clearly that the sensitivity of mountain and hillslope systems to climate is acute and that events beyond historical experience could occur (Goodfellow and Boelhouwers 2012).

5.15.2.1 Landslide-Induced Fatalities and Casualties

The number of fatalities (deaths and missing persons) and the number of casualties (deaths, missing persons, and injured people) are a direct quantitative measure of the intensity of a disaster and can be used to evaluate individual and social risk quantitatively (Salvati et al. 2010). Moreover, these quantities are highly relevant to landslides, debris flows, and flash floods, which correspond to high number of fatalities compared to other natural hazards. Guzzetti (2000) compiled a database of landslides that occurred in Italy between 1279 and 1999 and caused deaths, people missing, injuries, and homelessness. Analysis of the database indicates that more than 10 000 people died in a total of 840 landslide events. Fatal landslide events were more frequent in the Alpine regions of Northern Italy and in Campania (southern Italy), and most casualties occurred in the autumn. Fast-moving landslides caused the largest number of deaths. They included rockfalls, rockslides, rock avalanches, and debris flows.

5.15.3 A Large-Scale Characterization of Flash Floods Hazard in Europe

The large diversity in climate, synoptic conditions, and hydrological properties across the mountainous European terrain leads to large variability in the flash flood regimes. This heterogeneity combines with differences in social, economic, and institutional characteristics at local, regional, and national level to generate a complex pattern of impacts, responses, and mitigation policies for flash flood risk.

Marchi et al. (2010) has shown that flash floods are associated with physiographic factors that are typical of mountainous terrains. This is due to the combination of two main mechanisms: orographic effects augmenting precipitation and topographic relief promoting rapid concentration of streamflow. Both effects have been documented in the literature (Costa 1987; O'Connor and Costa 2004). Storm quasi-stationarity is a characteristic feature of several flash flood-generating rainfalls, with very intense precipitation insisting on the same locations for enough time to produce heavy accumulations. One of the elements that favors the anchoring of convective system is the orography, which plays an important role in regulating the atmospheric moisture inflow to the storm and in controlling storm motion and evolution (Smith et al. 1996; Borga et al. 2007; Davolio et al. 2009). Relief is necessary for promoting flow concentration along drainage ways, which results in high unit discharges and relevant geomorphic effects of flash floods in sloping watersheds. Heavy convective precipitation may occur also in plain areas, but the ensuing flood generally lacks the kinematic component, which characterizes the propagation and the hazard potential of flash floods.

To address the gap in available information, and particularly, to assess the possible ranges for peak discharges on small watersheds and to describe the geography of the hazard across Europe, an intensive data compilation has been carried out in the EU FP6 Research project titled 'Hydrometeorological data resources and technologies for effective flash flood forecasting' (HYDRATE, www.hydrate.tesaf.unipd.it, Borga et al. 2011). Data from seven European regions (Table 1) were considered. The data and analysis reported in this chapter update previous analyses reported by Gaume et al. (2009).

A definition of flash flood event was required as a working principle to develop the archive and select the events. An initial definition of flash flood event was based on the duration of the causative rainfall, the size of the catchment impacted by the flood, and the severity of the event. Consistent with the rules adopted by Gaume et al. (2009), the duration of the causative storm event was limited to 24 h and the maximum size of the catchment area was set to 1000 km^2. Rainstorm duration is defined here as the time duration of the flood-generating rainfall episodes, which are separated by less than 6 h of rainfall hiatus. As a follow-up, these rules were slightly relaxed to include one event with a larger catchment size (Gard event in France, 2002; with a maximum basin area of 1856 km^2).

Analysis of peak flow distribution and seasonality was carried out by collating and compiling the *primary data* on the reported flash floods. Primary data represent the minimal data structure required to qualify a flash flood event: occurrence data, location, peak discharge, and catchment area. Detailed

Table 1 Methods of estimating the flash flood peak discharges (%)

	Manning–Strickler formula estimation	*Extrapolation of calibrated stage–discharge relation*	*Hydraulic 1D simulation*	*Hydraulic 2D simulation*	*Reconstruction from reservoir operation*	*Direct current meter measurement*	*Other*	*Unknown*
Spain	56	11	33	0	0	0	0	0
France	20	33	17	0	7	0	0	23
Italy	64	23	13	0	0	0	0	0
Slovakia	0	73	0	0	0	0	27	0

Romania	0	53	0	0	47	0	0	0
Austria	0	94	6	0	0	0	0	0

precipitation data are often missing, because of the relevant estimation difficulties under flash flood conditions.

Validation of the data sets was carried out, when possible, by cross-checking reported rainfall accumulations with peak discharge estimates and identifying outliers from the rest of the data set for the region. Overall, intraregional comparisons and comparisons with other inventories did not reveal significant discordances in peak discharge estimates. The final data set includes 578 flood event records in seven European regions, as reported in Table 1, which also illustrates the methodology used for peak discharge estimation.

Although the data compilation aimed to be consistent and comprehensive in each region, the quality and quantity of data that could be collected varied from country to country, depending on the available sources of information and the institutional frameworks for collecting and recording data. The peak discharge computation methods and the corresponding discharge accuracy rate relate to the nature of the sources of information used. It can be noted that most of the discharge estimates in the catalogs for Austria, Slovakia, and Romania have been obtained from stage–discharge relationships, indicating that a large part of the data comes from gauging stations. In Italy and France, many estimates are based on hydraulic calculations, indicating that a significant proportion of the information is on ungauged sites and has been collected from scientific reports, papers, and studies. In most regions, the values closest to the envelope curve (see following discussion), correspond dominantly to ungauged sites, justifying the efforts for retrieving data from ungauged watersheds.

To enable first intercomparisons, the complete data set has been refined by selecting the most extreme events, identifying those events that are closest to the envelope curve for each region. The 30 events with the highest 'reduced peak discharge' (see next sections for a definition) were selected for each region, the reduced discharge formula being linked to the shape of the envelope curves. Several of the original data sets contained multiple records for the same rainfall event, distinguishing different peak discharge estimates at different locations within the affected catchments. In refining the data sets to 30 events, it was specified that no more than two records within the set of 30 should be of the same date in a region. This condition was selected to maintain a diversity of case studies and representativeness of the refined database.

Not all refined data sets selected meet the target number of 30 records, and the refined data set only counts 150 records over the seven considered regions (Table 2). Two indices help to compare the various data sets (reported in Table 2): the compilation coverage (watershed area multiplied by period considered) and the compilation density (number of documented events divided by the coverage). The periods as well as the areas covered by the inventories differ among regions. These features may affect the intercomparison in various ways. The number of observed events exceeding a given magnitude threshold increases on an average linearly with the considered area and period in a statistically consistent region if there is a temporal and spatial independence between events. The two conditions, consistency and independence, are not fulfilled, but the general conclusion remains valid. If we assume that the major floods have been reported in the inventory, the proportion of high-magnitude events in the 30 event sets will have a general tendency to grow with the coverage of the inventory.

This means that the Italian and Romanian inventories are more likely to contain higher-magnitude events. In contrast, this can be partly compensated by the density of the inventories for France and Slovakia; the proportion of missed extreme events, especially events that occurred on ungauged watersheds, reduces as the comprehensiveness of the inventory increases. As a consequence, the envelope curves are affected by the coverage of the inventories.

The magnitude of the most extreme floods defining the envelope curve has a general tendency to grow as the coverage grows. Likewise, the number of records close to the envelope curve increases with the density of the inventory.

5.15.3.1 Magnitude, Seasonality, and Space–Time Scales of Flash Floods in European Mountain Areas

Envelope curves provide an effective graphical summary of previous floods in a given region. They have been widely used in past publications on extreme floods (Herschy 2005; Castellarin 2007) and have the advantage of being relatively unaffected by the data compilation density because they are determined by the maximum values of a sample. Peak discharge data and the corresponding envelope curves have been plotted in Figure 3.

For the sake of clarity, a simple envelope curve equation, often used in previous studies, has been selected (eqn [2]). According to this equation, the envelopes appear as straight lines on the chosen log–log representation:

$$Q_s = \alpha A^{\beta} \tag{2}$$

Here Q_s is the unit discharge in $m^3\,s^{-1}\,km^{-2}$, A is the catchment area in square kilometer, α is a coefficient supposed to be

independent on the catchment area also called 'reduced' discharge in $m^3\,s^{-1}\,km^{-2(1+\beta)}$, and β is a scaling exponent. As suggested by Castellarin (2007), the value of the exponent β has been estimated through a linear regression between $\log(Q_s)$ and $\log(A)$ based on each of the refined data sets. An average value of $\beta = -0.4$ appears to be the best suited to the available data sets. It lies in the range of previously calibrated envelope curve parameters for various climatic contexts (Castellarin 2007).

5.15.3.2 Flash Flood Magnitude and Occurrence

The data sets mix peak discharge estimates from watershed areas ranging from some tens of square kilometers to about 2000 km^2. According to the adjusted envelope curves and especially the value of the power β (−0.4), a reduced peak discharge Q_r has been selected as the indicator of the magnitude of the floods to aggregate the data and limit the influence of the watershed areas on the analyses: $Q_r = Q/A^{0.6}$. Q is in $m^3\,s^{-1}$; A, in km^2; and Q_r, in $m^3\,s^{-1}\,km^{-2\times0.6}$. The atlas of extreme floods over mountainous Europe thus plots the reduced discharge of events in each region (Figure 4).

The atlas maps the spatial distribution of flash floods in the seven areas included in this study. The differences appearing on this map are confirmed by examining the proportion of the flash flood events in each reduced discharge category for each considered region based on analysis of the refined data sets (Table 3). There appears to be a significant proportion of events of over 75 $m^3\,s^{-1}\,km^{-2\times0.6}$ in France (13%), northern Italy (17%), and Catalonia (11%). The lower category events ($Q_{ps} < 25\,m^3\,s^{-1}\,km^{-2\times0.6}$) represent a minority in these regions. This lower category represents three-quarters of all other inventories. This shows that Mediterranean flash floods are characterized by higher magnitude (when referred to the catchment area) with respect to the other European regions considered here.

5.15.3.3 Flash Flood Seasonal Distribution

The inventory also provides information on the patterns of seasonality of flash floods over the European regions. The number of records reported for each month is shown for each region in Figure 5 (in which events in Greece are not reported because of their reduced number). The extreme floods in Catalonia and France, without exception, occurred in autumn, whereas in the Central European countries (Austria, Slovakia, and Romania), these extremes occur only in the late spring and summer seasons. Northern Italy lies in an intermediate position with a dominant proportion of extreme floods in autumn and some in spring. This feature is not modified if the complete data set is taken into account. This difference in the seasonality shows that the most extreme flash floods in the Mediterranean and in the inland continental regions are not induced by the same types of meteorological events. Flash floods in the study area encompass a diversity of meteorological and hydrological processes.

Intense autumn storm events delivering very high amounts of rain water within a short period and sometimes over large areas appear to be a specificity of the Mediterranean area. Intense summer thunderstorms also take place frequently in this area. But they almost never induce significant floods, because of the high infiltration capacities of the dry soils in the summer season. The initial wet conditions of the watersheds can play a major role in the flash flood response to a rainfall event (Marchi et al. 2010). These conditions are linked to the climatic settings and can also explain the differences observed between the hydrometeorological regions. In the same line of thinking, Merz and Blöschl (2003) found that flash floods in

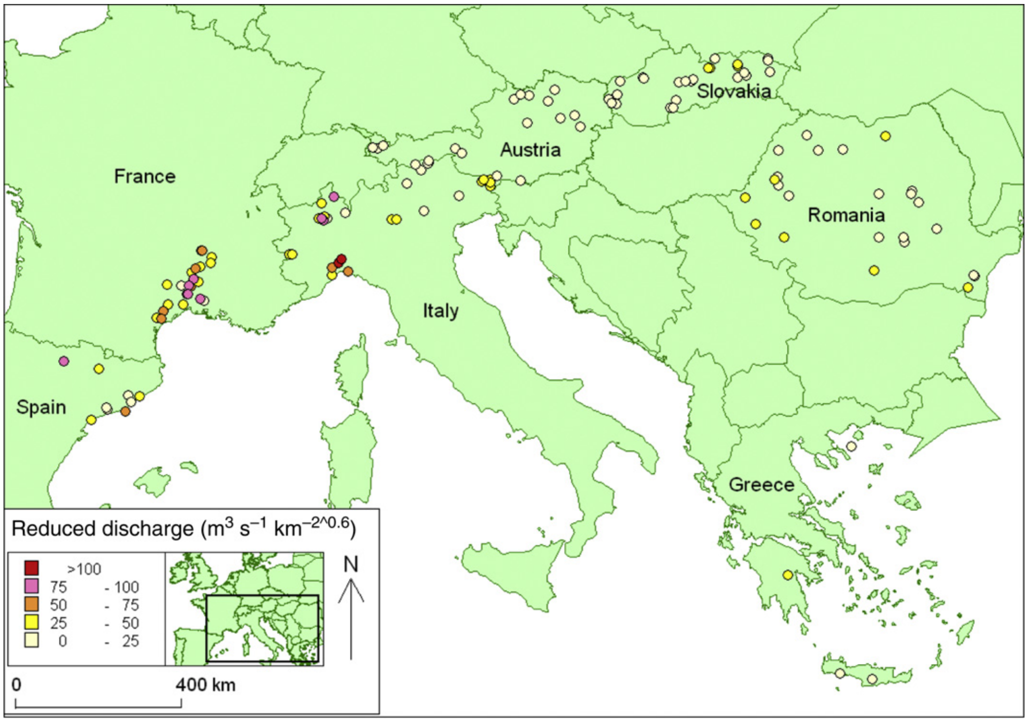

Figure 4 Atlas of reduced peak discharges of extreme events in Europe.

Austria are most extreme in the eastern part of the country, which corresponds with the flash flood atlas presented here. These authors suggested that the hilly terrain in this region increases the instability of the boundary layer and therefore increases the potential for convective storms.

5.15.3.4 Flash Flood Fatalities

The difficulties in developing homogeneous information on flash floods are also reflected in the fragmented information about flash flood-related fatalities. Among the few systematic studies with a continental view, Barredo (2007) reports a catalog of the major flood events since 1950–2006 in the European Union. In his study, he characterized major floods in terms of casualties and direct damages. Of the 47 events listed in the catalog, 23 are classified as flash floods, and are mainly localized in Italy, Spain, and southern France. Flash flood events are also reported in Germany, Belgium, and the United Kingdom. In spite of the smaller areas affected by these events, flash floods caused 2764 fatalities – that is, 52 casualties per year on an average, which is close to the annual statistic reported for the United States by Ashley and Ashley (2008).

Table 3 Proportion of events in each pseudo-specific peak discharge category in the refined data set (%)

	0–25	*25–50*	*50–75*	*75–100*	*>100*
Catalonia	45	33	11	11	0
France	17	43	27	13	0
Italy	33	43	7	10	7
Slovakia	87	13	0	0	0
Greece	75	25	0	0	0
Romania	77	23	0	0	0
Austria	100	0	0	0	0

The number of flash flood-related fatalities represents 40% of the overall casualties reported in the study, largely exceeding river floods (18%), and being second only to storm-surge floods (42%). Fatalities due to storm-surge floods concentrate into three extreme events that occurred from 1953 to 1962 on the coastal regions of northern Europe, whereas flash floods have been reported over the wider period (1950–2006) and across the whole European region. It should be noted that, given the focus of the study on major events, flash flood casualties were likely underestimated by Barredo (2007).

5.15.4 Conclusions and Indication for Future Work

Landslides, debris flows, and flash floods have been examined in this chapter as natural hazards that are typical of mountainous areas in Europe. A description of the main characteristics of these hazards has been given based on catalogs obtained by integrating various sources of information.

The data catalogs mentioned in the chapter may be developed further by extending the inventories within the existing regions and also by including other countries within the database. With the introduction of the European Floods Directive in 2007 requiring the EU member states to have prepared flood risk maps by 2013, there is likely to be an increase in efforts to research and document historic floods and related hazards as part of the work done to meet the Directive. This may enable access to data that was not readily available to this study. In addition, to expand the data catalog, it may be

interesting to further develop the analyses of the data. This may include statistical approaches to draw intercomparisons of the data, especially to reveal the heterogeneity of the data between and within the considered regions and to evaluate the return period of the reported extreme events.

The assessment of landslides/debris flows and flash floods provides indications for risk management strategies. While warning systems can substantially assist in reducing loss to life and property, they need to be integrated into a more general framework of flood risk management. Other risk management tools are complementary to warning systems. Also, there will be instances when there is not enough warning time and people may not be reached or will ignore warnings. Similar to the forecasting and warning component, risk management should be based on a fully integrated approach that recognizes the specificities of the hazardous floods. These include (1) the difficulties to rely on traditional physical flood defense infrastructure; (2) the multihazardous nature of debris flows/flash flood risk, particularly when it involves mountainous settings; and (3) the need to develop specific preparedness strategies that incorporate event management.

The identification of debris flows/flash flood risk areas should inform the risk management process. The difficulties of relying on flood protection works place emphasis on land-use planning and flood event management. It is important to combine these two steps of risk management into one synthesized plan to enable the sharing of information between land-use planning and civil protection authorities and to exploit the synergies between these two management fields. Risk management consists of systematic actions in a cycle of preparedness, response, and recovery, and this should also be reflected in land management approaches. Long-term risk management needs to address the tensions between risk management and economic development. Embracing scenarios of the future (including climatic, demographic, and socioeconomic changes) within the decision-making process is required to identify precautionary, sustainable, and adaptable risk mitigation policies and strategies.

Accounting for the multihazard nature of debris flows/flash floods is particularly important. Often, flash floods, landslides, and debris flows occur in conjunction, which may cause amplification of the hazard – for instance, by inducing drastic changes in stream bed morphology during flash flood events. However, mapping of flood risk zones, which is an essential element in many national legislations, is generally based only on flood hazard assessment. There is therefore a need to develop a multirisk approach that can tackle possible 'simultaneous' and 'cascade' effects due to coincident, or induced, occurrence of flash floods, landslides, and debris flows that amplify the risk in some areas, and may be not accounted for by single hazard estimations.

5.16.1 Environmental Change and Its Impact on Floods

Floods are a major threat to human existence and severely affect populations across the globe (Mustafa 2007). Understanding, predicting, and mitigating the impacts of floods is thus a very important activity, but one that is rife with challenges. Floods and floodplains are dynamic and nonstationary systems. River channels and floodplains constantly change as a result of natural erosion, deposition, and channel migration processes. Additionally, they change because of external factors such as increased population pressure and demand for land for various human activities, desire for mitigating and managing floods, and climate variability and/or human-induced climate anomalies. These factors can lead to changes in flood characteristics, such as flood intensity, velocity, time to peak, and risks to which people and property are exposed (Bradshaw et al. 2007; Blaikie et al. 2004; Vojinovic and Abbott 2012).

Hazardous flooding can be defined as having too much water in the wrong place and/or at the wrong time and as such is a problem generated by humans. Excess water can occur on the land surface as a result of a variety of process drivers including extreme rainfall, river flow, groundwater emergence, dam breaks, or the combined effect of astronomical tides and storm surges. Such water *sources* are conveyed along a variety of *pathways* (as overland flow, through the subsurface, in rivers or over fluvial and coastal floodplains) to *risk receptors* where the adverse effects of flooding occur. This *source-pathway-receptor* model therefore defines the types of floods that hydrologists typically refer to: flash floods, dam break floods, fluvial or river floods, groundwater floods, and coastal floods. Flooding is therefore driven by a variety of physical processes, and it only becomes a problem when either economic damage or threats to human life, well-being, and security occur.

5.16.1.1 The Two-Faced Flood

Floods are the most common environmental hazards and cause more damage than other hazards including earthquakes, volcanic eruptions, and tsunamis (Kusky 2008). During severe weather events, flooding can be part of a *hazards complex* that includes mudslides, gales, and tidal surges that cause compound devastation (Few 2003). Floods are not just monstrous hazards that happen once in a lifetime, but their frequency and wholesale influence can affect any corner of the world, making them the worst kind. Low-magnitude high-frequency floods can lead to damage to farm land, disruption or destruction of infrastructure and facilities, suspension of

http://dx.doi.org/10.1016/B978-0-12-384703-4.00508-6

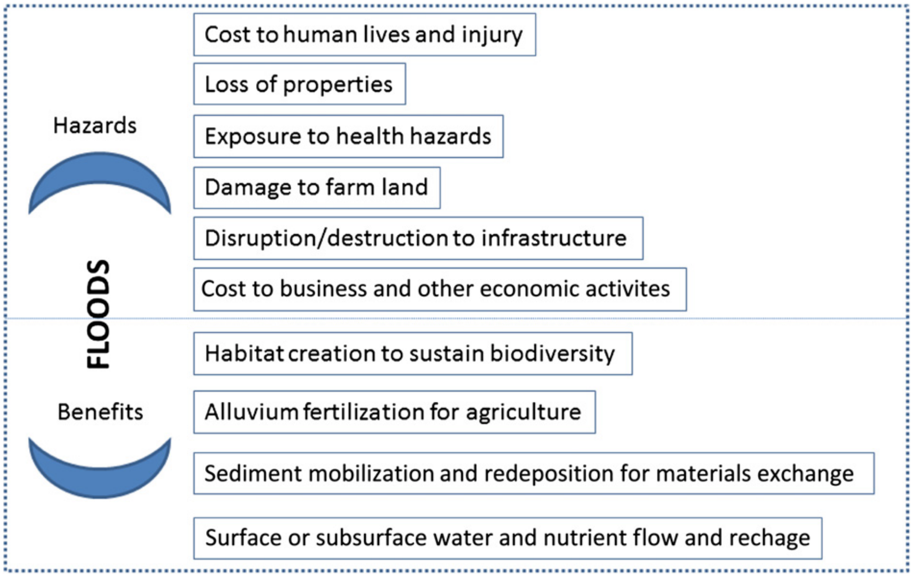
business and other activities, exposure to health risks, and so on (Few 2003). A plethora of media documents facts and figures concerning flood damage to human lives, livelihoods, and property. It is unsurprising that floods, by default, are associated with words such as *disaster*, *catastrophe*, and *hazard*, and flooding itself can thus also be defined in terms of the *potential*, *experience*, and *aftermath* of this environmental hazard (Mustafa 2007).

The nature of floods is, however, two-faced (Few 2003). Despite being perceived as a 'hazard,' humans have coevolved and coexisted with floods and floodplains. Floodplains have always been favored sites for human settlement because of their multiple functions in providing drinking water, hydropower, sites for waste disposal, fertile soils for agriculture, navigation waterways, flat terrain for building, 'waterfront' view, and leisure activities, and so on (Alexander and Marriott 1999; Bridge 2003). Floods can also bring extensive economic and environmental benefits, although often less acknowledged by people (Blaikie et al. 2003; Smith, 1996; Handmer et al. 1999; Alexander and Marriott 1999; Bridge 2003). These include habitat creation to sustain biodiversity, alluvium fertilization for agriculture, sediment mobilization and redeposition for materials exchange, and surface or subsurface water recharge and nutrient circulation. It is therefore reasonable that many residents of developing countries perceive floods with an ambivalent attitude and prefer 'living with floods' to engineering measures that prevent them (Few 2003). In fact, this is increasingly true for all people as the desire for sustainable or green living takes root in the world. Figure 1 summarizes both the hazardous and beneficial features of floods.

5.16.1.2 Climate and Flooding

Currently, one of the most politically discussed environmental changes that may affect flood dynamics and vulnerability is changes in the frequency of floods. Climate variability and longer-term change, be it artificial or natural, long- or short-term variation (Box 1), is one of the major causes of significant trends in the occurrence of flooding over time (Smith and Ward 1998). Time scales can range from short term, for example, seasonal variation, and a cluster of a number of dry/wet or warm/cold years, to decadal, centennial, and millennial variations or even multimillennial variations. Depending on the time scale and location of these changes, impacts on flooding characteristics and resulting consequences on human beings and ecosystems can be very different.

Climate-related flooding during prehistorical and early historical times has often been associated with significant impact on human settlement including field abandonment and consequent cultural adaptation (exchange, collapse, or emergence of new culture) (Fagan 2000). A number of these examples are presented in Section 5.16.3.1. The prehistorical and early historical climate variability is largely attributed to natural fluctuations of geophysical processes. This signal is now altered by human-induced climate effects. At present, our limited knowledge and understanding of Earth sciences, and the complex interactions between atmosphere, hydrosphere, and other Earth subsystems make it nearly impossible to differentiate climate-related floods caused by human-induced change from those caused by natural background variation. There is potential for intensive precipitation increases if the water holding capacity (of the atmosphere) increases with warming on a global scale (Kundzewicz and Schellnhuber 2004). This could translate into increased flood risk and vulnerabilities (Milly et al. 2002; Wilby et al. 2008; Vojinovic and Abbott 2012). A set of possible links between contemporary human-induced impacts on climate and flooding have been discussed extensively by the Intergovernmental Panel on Climate Change (IPCC) from the First Assessment Report (IPCC, 1990), through to the Fourth Assessment Report (IPCC, 2007), and the Summary for Policymakers (SPM) for



Hazards
FLOODS
Benefits
Cost to human lives and injury
Loss of properties
Exposure to health hazards
Damage to farm land
Disruption/destruction to infrastructure
Cost to business and other economic activites
Habitat creation to sustain biodiversity
Alluvium fertilization for agriculture
Sediment mobilization and redeposition for materials exchange
Surface or subsurface water and nutrient flow and rechage

Figure 1 Illustration of the 'two-faced nature' of floods bringing with them both hazards and benefits.

Box 1

Definitions of Climate Change

Climate change is defined by the United Nations Framework Convention on Climate Change (UNFCCC) in Article 1 as:

> *"a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods"* [United Nations General Assembly, 1992].

Climate change is defined by the Intergovernmental Panel on Climate Change (IPCC) as:

> *"a statistically significant variation in either the mean state of the climate or its variability, persisting for an extended period (typically decades or longer)"* [IPCC, 2001].

or

> *"a change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties and that persists for an extended period, typically decades or longer"* [IPCC, 2012].

UNFCCC makes a distinction between climate *change* and climate *variability*. The former is solely related to anthropogenic influence, and the latter is due to natural fluctuation of underlying physical processes. In contrast, IPCC suggests a change in climate, as long as it can be identified by statistical measures, is climate change, disregarding causes. UNFCCC does not specify the time scale of a typical climate being considered by stating *over comparable time periods*, while IPCC spells out *decades or longer*, although similarly ambiguous.

The use of the term 'climate change,' however, obscures that the fact that climate is never static, and frequencies of flood events, for example, have variations on all time scales (e.g., Rial et al. 2004). It is the total climate effect that affects the resource.

the IPCC Special Report on Managing Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (IPCC, 2012).

Such studies are valuable attempts in the bid to understand the impacts of climate on flooding; however, they have two major limitations. The first lies in the highly uncertain predictions of flood risk emanating from climate models because of current unsatisfactory and patchy understanding of Earth system science, insufficient observational data, inadequate computing resources, indecisive emission scenarios, and a plethora of other subjective decisions that are involved in climate impact modeling, and translation of model results in predicted risk from climate variability and longer-term change (Reynard 2007; Hulme 2009; Beven 2011). These uncertainties in the climate impact projections on flood hazard and risk are thus from both a physical science and a human perspective not well characterized (Beven 2009), and adaptation strategies, which are often heavily based on modeled projections, may fall short and leave humans more vulnerable to flood risk. The second limitation is that, although some conclusions may be claimed for large-scale river basins (based on climate model output), it is extremely challenging to make any general conclusion for small- to medium-sized river basins or local regions (Beven 2011). Global or large-scale studies may be of less interest to adaptation because flood risk is very much location, activity, and value dependent (Swart and Vellinga 1994; Parry et al. 1996; Jones 2001) and adaptation to changing risk should be worked out within a regional or local context while also taking into consideration the responses of individual catchments. The current generation of climate models is far from being skillful in resolving small-scale physics (microphysics of convective activity, orography, and subtle but relevant feedbacks attributable to detailed topographical characteristics). Studies on climate impacts on flooding at regional and local scales remain, at best, overly ambitious exercises when based on current climate models. Section 5.16.2 reviews modeling tools that are used to study the effects of climate on floods.

5.16.1.3 Landuse Change and Flooding

Alongside climate variability and longer-term change, landuse change is the other major factor that can make humankind and ecosystems more vulnerable to flooding. Human reshaping of land cover has increased at a staggering rate. The change is *unprecedented in magnitude and rate* and has *significant impacts on the biogeochemical systems that sustain the biosphere* (William and Turner 1992). Every day more natural land is taken to be converted to an artificial state for various types of human activities and needs. Figure 2 shows an example of how much land was modified annually through human activities from 2000 to 2006 in selected European countries (The countries include Albania, Austria, Belgium, Bosnia and Herzegovina, Bulgaria, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Hungary, Iceland, Ireland, Italy, Latvia, Liechtenstein, Lithuania, Luxembourg, Macedonia the former Yugoslavian Republic, Netherlands, Norway, Poland, Portugal, Romania, Serbia, Slovakia, Slovenia, Spain, Sweden, and Turkey). The overall area that was created during this period came up to 111 788 ha year^{-1}.

It is clear that world population growth is the driving force behind the accelerated landuse change (Box 2).

Of all land cover modification, floodplain development is of particular concern, as the frontline of defense against flooding has been largely compromised. In addition to the benefits of living on or near floodplains, rapidly increasing population leaves humankind no choice but to occupy more of the floodplains. Floodplains have precisely the function that their name suggests that rivers can be expected naturally to flow beyond their banks every few years (Wheater and Evans 2009). Floodplains provide natural storage and dampened release for excessive water and would only constitute a 'hazard' when

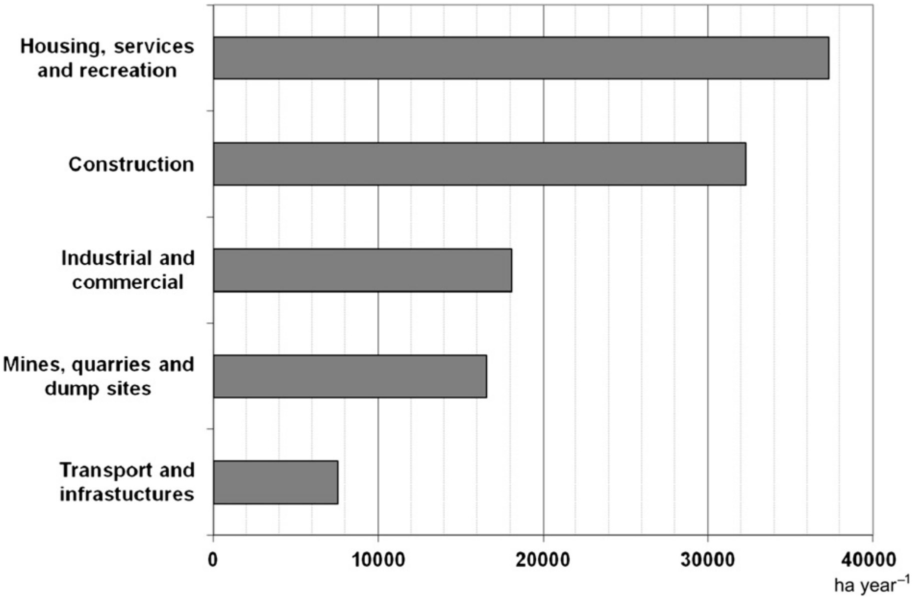


Figure 2 Annual land (hectares per year) taken by various types of human activities in selected European countries from 2000 to 2006. Data source: The European Topic Centre on Land Use and Spatial Information (ETC/LUSI) LEAC Database (based on the Corine Land cover 2000–06 changes, version 13, 02/2010).9.

Box 2

Major findings on world population and landuse from two recent studies conducted by Goldewijk et al. (2009, 2011)

- From 10 000 BC to AD 2000, the global population increased from 2 to 6145 million people, resulting in a global population density increase of <0.1 capita km^{-2} to almost 46 capita km^{-2}.
- From 10 000 BC to AD 1000, cropland occupied roughly less than 1% of the global ice-free land area, similar to the area used for pasture.
- In the centuries that followed, the share of global cropland and pasture area increased to 2% each in AD 1700 and 11% and 24%, respectively, in AD 2000.

---

encroached by humans (Smith and Ward 1998). Floodplain development for human consumption has noticeably downgraded or eradicated their ability to provide ecosystem services and functions: vegetated soils being replaced with impermeable surfaces, riparian forests being replaced by agricultural land, meandering channels being straightened, and so on. Consequences are manifold, for example, reduced infiltration and groundwater recharge, increased overland flow and runoff intensity, shortened travel time, and quickened flood onset (Morris and Wheater 2007). Unfortunately, much floodplain development coincides with development of urban and/or coastal areas. As population growth reduces the likelihood of returning floodplains to their natural states, scientists, engineers, landscape planners, and policy makers face a daunting challenge to find solutions for people to live with floods and reduce vulnerability. Section 5.16.3 Changing Flood Risk and Vulnerability elaborates on flood risk and vulnerability and measures for living with floods and building resilience.

Landuse change is not an isolated factor that acts on its own. Land, as a significant component in the Earth's system, interacts with other subsystems such as the atmosphere, biosphere, oceans, and cryosphere. It modifies the weather and climate through emissions of various greenhouse gases and exchanges of energy, water, and momentum between the land surface and other Earth subsystems (DeFries and Eshleman 2004). Readers can refer to Cotton and Pielke (2007) for a comprehensive exploration and detailed discussion on the climate forcing and feedbacks related to human-induced landuse change at both regional and global scales.

Impacts of climate variability on the water cycle and flooding are better researched than the effects of landuse change. It is perhaps due to the lack of knowledge of how to assess impacts of landuse change in combination with climate, unavailability of past landuse data as baselines, and limited understanding and predictability of human actors' responses to changing flood risk from landuse change. Because of the complex interaction between land and other Earth subsystems, it is vital not to detach impact studies of landuse from those of climate for assessment of future flood risk.

In summary, landuse change is a major human-induced stress factor on the environment. Unprecedented population growth, in parallel with major shifts in global affluence, technological capacity, and socioeconomic organization, is a significant driver of the contemporary landuse change (William and Turner 1992). Consequent changes in the flood characteristics and risks associated with land alteration can result from (1) interaction of landuse change with changes in greenhouse gas emission and radiative forcing that contributes to climate variability and longer-term change and (2) changes of catchment properties including vegetation cover and river channels.

5.16.2 Flood Inundation Dynamics and Impact Modeling

In this section, we are primarily concerned with river or fluvial floods as there has been much recent research into flood inundation dynamics and impacts of environmental change in this area.

5.16.2.1 Flood Inundation Dynamics and Modeling

The physics of floodplain inundation remains a challenge to scientists (Bates et al. 2012). Recently, laboratory experimentation (e.g., Knight and Shiono 1996; Sellin and Willets 1996), field experimentation (e.g., Babaeyan-Koopaei et al. 2002; Nicholas and Mitchell 2003), and remote sensing observations (e.g., Alsdorf et al. 2000, 2007; Bates et al. 2006; Pavelsky and Smith 2008; Schumann et al. 2007,2008a,b) have all resulted in significant advances in understanding of floodplain processes. We now understand much more about turbulent flow around structures during overbank flood flows and the dynamics of shallow plain flooding over complex topography.

The best representation of the physics that is currently conceivable would be to numerically model both river channel and floodplain flows as being fully three dimensional (3D), including turbulence, with solution of the full Navier–Stokes equations. However, for typical flood wave flows, this is prohibitively expensive from a computational point of view. Thus, only those hydraulic processes that are dominant in flood river routing and inundation prediction are currently represented in the most commonly used flood inundation models (Ingham and Ma 2005; Bates et al. 2012). Present understanding suggests that river channel flow may be treated as one dimensional (1D) in the downstream direction but flow on the floodplain when the river goes overbank must be treated as at least a two-dimensional (2D) process (localized zones require 3D representation of turbulent flow), and that flow paths cannot be well predicted a priori (Bates et al. 2012). With 1D model being much of the mainstream, for example, HEC-RAS, there are a number of models representing combined 1D/2D (e.g., TUFLOW, LISFLOOD-FP), 2D (e.g., TELEMAC-2D, SRH-2D), or 3D model (e.g., TELEMAC-3D).

In solving the differential equations of fluid dynamics, several (sometimes subjective) choices need to be made about the discretization of space and time. In terms of spatial discretization, a number of methods are used in computational fluid dynamics, and the three main methods are finite differences, finite elements, and finite volumes. Temporal discretizations are used to find solutions for simulation of unsteady state flows. Readers can refer to Wright (2005) for more details on discretization methods. The selection of discretization in space and time is also dependent on the resolution of available flow data, terrain data, the length scales of terrain features in the domain, and the length and time scales of relevant flow processes. As Bates et al. (2012) note, with the development over the past decade of high-resolution mapping technologies such as airborne scanning laser altimetry, terrain data are usually available at scales much finer than it is computationally possible to model over large areas. However, deciding which terrain and flow length scales need to be incorporated in a model is a much more subjective choice. Clearly, as spatial resolution becomes coarser, particular terrain and flow features will no longer be adequately represented and the impact of these sub-grid scale effects on the model predictions will need to be parameterized (Horritt 2005).

The LISFLOOD-FP model is mainly discussed below as a type of flood inundation model that is capable of capturing 2D complex processes using the raster based approach that is much faster than finite difference or finite element approaches but offers similar level of performance. The LISFLOOD-FP model has been designed to simulate propagation of water over complex topography typically represented by raster data (Bates and De Roo 2000; Hunter et al. 2005; Bates et al. 2010). It is a coupled 1D/2D flood inundation model. The channel flow can be represented using either a 1D kinematic or diffusion wave solved for a rectangular channel cross section using a fully implicit Newton–Raphson scheme. When bank full depth is exceeded, channel flow is transferred to the overlying floodplain raster grid over which flow can evolve in two dimensions. For the 2D floodplain flow, the current version of the model consists of a collection of numerical schemes implemented to solve a variety of mathematical approximations of the 2D shallow water equations of different complexities (ranging from an extremely simple diffusive wave model to a shock capturing Godunov-type scheme based on the Roe Riemann solver, which solves the full shallow water equations). Among these different formulations, the one that was proposed by Bates et al. (2010) has attracted increasing attention for modeling flood propagation over large urban areas. It solves a simplified inertial version of the St. Venant equations, which neglects the convective acceleration term in the momentum conservation equation, yielding a system of two partial differential equations:

$$\frac{\partial h}{\partial t} + \frac{\partial q}{\partial x} = 0 \qquad [1]$$

$$\frac{\partial q}{\partial t} + gh\,\frac{\partial (h+z)}{\partial x} + \frac{gn^2q^2}{h^{7/3}} = 0 \qquad [2]$$

where h is the flow depth [L], t is the time [T], q is the flow per unit width [L^2T^{-1}], x is the distance in the direction of flow [L], g is the acceleration due to gravity [LT^{-2}], z is the bed elevation [L] and n is the Manning's friction coefficient [$L^{-1/3}T$].

The resulting model provides a robust solution to subcritical flood propagation problems over complex topographies at relatively low computational cost.

Recent attempts to represent the processes of importance in flood inundation dynamics with flood inundation models such as the LISFLOOD-FP model have proved successful, even for complex rivers and urban landscapes (Pappenberger et al. 2007; Neal et al. 2011). With the advancement of flood inundation models, a reasonable confidence can be gained in modeled predictions of flood inundation dynamics, although there remain many limitations with respect to data input, process representation and underlying equations, numerical solutions, and computational power.

5.16.2.2 Climate Impact on Floods

It is well understood that climate variability and longer-term change in combination with landuse change would lead to a change in future flood vulnerability (Hulme et al. 2002; Huntington 2006; Wheater, 2006; Frey et al. 2010); however, it is the exact nature of this change in vulnerability that is elusive. This may involve increased economic losses due to damage to infrastructure, property, and agricultural land and indirect losses in or beyond the flooded areas. They can be production losses caused by damaged stock or roads (Linnenluecke et al. 2011), or the interruption of power generation and navigation (Yamba et al. 2011) or just as importantly, the access to renewed livelihoods and homes (social justice) for those flooded, or the sense of well-being and security and changes in risk perception (e.g., Harries 2008). Thus, estimates of flood vulnerability over the next approximately 100 years are essential for planning adaptation and mitigation strategies (Evans et al. 2004). Climate impact on flooding could occur through several pathways: changes in sea level (e.g., a projected sea level rise) could lead to an increased risk of flooding in the coastal areas (Zanuttigh 2011), an increased intensity and frequency of extreme precipitation could lead to an increase in fluvial floods and flash floods, and seasonal precipitation or temperature changes affect snow melt patterns (e.g., Milly et al. 2005; Huntington 2006; Alcamo et al. 2007; Kundzewicz et al. 2005).

There is now a very large body of research that discusses the impact of climate on floods (a few examples being Kay et al. 2006; Bell et al. 2007; Dankers et al. 2007; Graham et al. 2007; Leander et al. 2008). Some of the studies predict an increase in flood frequency, whereas the others report a decrease. This is a reflection of the facts that many hydrological studies focus on individual catchments or small areas, and the complexity of the hydrological phenomena, which means that the 'theoretical expectations' (e.g., more precipitation equals more flooding) are not necessarily supported by empirical evidence to date (Huntington 2006). In addition, it illustrates the inherent uncertainties in climate projections. Therefore, there is an increasing recognition that the uncertainties in climate impact studies need to be rigorously quantified and that a simple estimate of uncertainty is inadequate and could be misleading.

Policy makers need to be presented with reasonable assessment of uncertainties together with cost-loss evaluation as well as vulnerability estimates of taking action or not (Diez et al. 2005). The most popular tools to quantify climate are Global Climate Models (GCMs), but climate modeling is by nature an inherently uncertain activity (Collins et al. 2006). GCMs have had very limited or even no success representing local and regional conditions essential for impact studies (e.g., Semenov 2007; Stephens et al. 2010; Anagnostopoulos et al. 2010). When projections from GCMs are combined with a model cascade (Figure 3) of downscaling models, correction techniques, rainfall-runoff models, and flood inundation models and linked to indicators of vulnerability, the uncertainties involved can be significant and effectively unknowable. It is paramount in impact studies to have a transparent estimate of all uncertainties, which (1) assesses all components contributing to uncertainties, (2) quantifies the combined global uncertainty of the flood vulnerability calculation (the combined uncertainty at the end of the model cascade), (3) acknowledges explicitly the inevitable assumptions that must be made, and (4) quantitatively assess the skill of the models to predict (in a hindcast mode) changes in climate statistics that matter to the floods. It can go some way to dispel skepticism about future climate predictions (Stainforth et al. 2005; Thorpe 2005) and thus future flood vulnerability. It can also enable adaptation decisions to be made more intelligently (Dessai and Hulme 2007). However, there remain scientific challenges in actually achieving a rigorous quantification of uncertainties, because of, for example, complexities in the physical processes, lack of observational data, and constraints in computational time.

Many recent climate impact studies for flood hazard have followed this general framework of a model cascade approach (Cameron et al. 2000; Cameron 2006; Bell et al. 2007; McMillan and Brasington 2008). It is also common in other areas of hydrological science such as flood forecasting (Pappenberger et al. 2005; He et al. 2009). Continuous predictions of meteorological variables (especially rainfall), or stochastic representations of such, are used to drive hydrological and/or hydraulic models to calculate flood inundation extent, water depth, velocity, duration, sediment load, and other variables, which can be transformed to estimates of flood hazard. This type of model cascade approach to assess climate impacts is referred to as the *top-down* (largely adopted by the IPCC investigation and reporting process) or *scenario-led* (Prudhomme et al. 2010) approach. It is a hierarchical approach starting from GCMs driven by future emission scenarios, moving to downscaling and bias correction approaches, and finally cascading to impact models. It is a loosely coupled modeling assembly that can only provide an interim solution to assess impacts of climate on floods and a limited number of snapshots (Jones 2001) of future flood risk projected through time. The uncertainties involved in the model cascade could potentially lead to ineffective flood

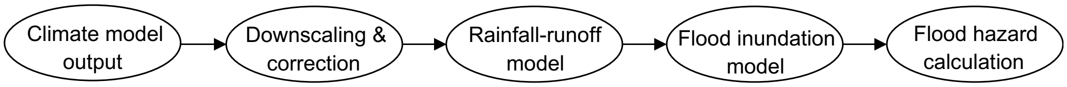

Figure 3 Simple schematic of the linear sequence of a model cascade approach for assessing climate impacts on flood hazard.

management strategies (see discussion in van Pelt and Swart 2011; Blöschl et al. in press). Pielke and Wilby (2012) discuss in more details the limitations associated with this type of approach.

An alternative approach is called the *bottom-up* (Jones 2001) or *scenario-neutral* (Prudhomme et al. 2010). It superimposes every individual flooding impact point resulting from climate model cascades, historical events, recent paleo events, and worst-case sequences of observed weather patterns on a river catchment response surface that covers a plausible collection of changes in response to environmental changes (stresses when their impacts are perceived negative) (Jones 2001; Prudhomme et al. 2010; Wetterhall et al. 2011). The bottom-up impact studies are based on sensitivity analyses of catchment responses to a plausible range of climate (Prudhomme et al. 2010). If all changing factors are considered, a multidimensional catchment response surface is expected to be constructed. The mitigation strategies based on the bottom-up approach may not be optimal from an economical point of view but can be more robust and with *less regret* (Blöschl et al. in press). Readers can refer to Blöschl et al. (in press) for a more detailed comparison between top–down and bottom-up approaches applied in hydrological impact studies.

5.16.2.3 Flood Risk Communication and Visualization

Risk communication is central to international disaster risk reduction strategies (e.g., UN/ISDR 2004; IKSR 2005; IFRC 2009; Pitt 2007), because preparedness and response measures depend not only on the soundness of the underlying scientific risk assessment but also on how effectively the risk information can be conveyed to those responsible for acting on it. Given the potential for scientific error, it is now increasingly recognized that communicating uncertainties associated with probabilistic forecasts is as important for risk management as increasing their accuracy and timeliness (NRC 2006). In the specific context of hydrometeorological climate modeling, formal assessments of uncertainties are thus now a prominent feature of meteorological, hydrometeorological, and climatological research and operational forecasting. While important technical advances have been made in the ability to characterize and quantify hydrometeorological forecast and climate uncertainty, new tools are required to translate this information into clear and effective visualizations that can be easily communicated to decision makers and the general public at large. One example in which such uncertainty is displayed is in operational flood forecasting (Cloke and Pappenberger 2009). Experience in this and other domains suggests that the design and framing of uncertain information is important in shaping how it is understood and acted upon by recipients (NRC 2006). There is also an extensive body of research on how the probability of precipitation forecasts is understood by the general public (Murphy et al. 1980; Gigerenzer et al. 2005; Morss et al. 2008), as well as research on public response to the idea of the 100-year flood (Bell and Tobin 2007) and to the cone of uncertainty visualizations used by the US Hurricane Center to communicate the likelihood of different storm track paths (Broad et al. 2007). Proceeding from an implicit 'deficit model,' much of this work has focused on how the design of risk messages can improve public understanding of scientific uncertainties (Demeritt et al. 2011). However, it is increasingly clear that hydrometeorological climate forecasters (Doswell 2004; Elia and Laprise 2005; Demeritt et al. 2007), like other professional groups (Kostopoulou et al. 2009), are not immune to cognitive and other biases that may distort their understanding of uncertainty and risk. So there are calls for more attention to be paid to the communication of uncertainty of flood vulnerability between different professional groups (i.e., from meteorologists to hydrologists, and from hydrologists to civil protection authorities) involved in flood incident management (Faulkner et al. 2007). There are a number of different ways in which such information could be displayed. Different users are likely to require different kinds of information and thus different visualizations. Expert users may require access to multiple parameters, such as previous observed values, skill scores, and the full uncertainty, all combined in a single information-rich display, whereas other users may prefer simpler displays showing the probability of threshold exceedance and vulnerability. An example of the type of information-rich display is shown in **Figure 4**. Being a simple and quick sketch made in an expert elicitation workshop, it captures the message that this expert user, whose desire possibly represents that of many other expert users, requires not only the corresponding probability of a specific forecast but also the consequence of that particular forecast. It is worth noting here that this information is implicitly based on probabilistic forecasts, not a conventional deterministic forecast. Probability and consequence are the two building blocks for constructing the risk of a forecasted flood event, which will be discussed in Section 5.16.3. Future research will need to put more emphasis on how uncertainties in vulnerability can be displayed and communicated in a more effective way.

5.16.3 Changing Flood Risk and Vulnerability

Flood risk and vulnerability remain at the core of the flood disaster debate. Disaster risk management is discussed by using a variety of terms such as risk, hazard, exposure, vulnerability, coping capacity, resistance, resilience, and adaptive capacity (Merz et al. 2010). On most of these terms, there is no consensus (e.g., Gallopin 2006; Cutter et al. 2008). Against this background, a deliberate attempt is made at defining all terms used in this section of the chapter.

Understanding future flood risk would require a multidisciplinary approach, combining expertise across climate science, catastrophe modeling, economics, and policy (Herweijer et al. 2008). In a nutshell, flood risk and vulnerability in the twenty-first century and beyond will be affected by the following drivers (in order of importance):

1. Population growth
2. Landuse change
3. Urbanization
4. Economic growth in developing countries
5. Rising sea levels.

The alarming reality is that both flood risk and vulnerability are changing for the worse.

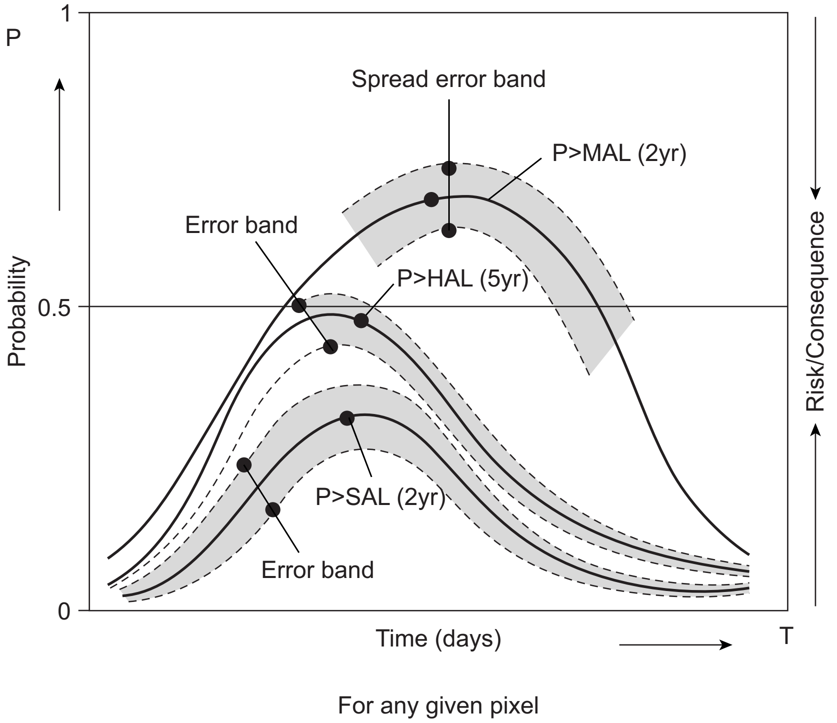

Figure 4 Drawing from an expert election study displaying all components that need to be on a flood forecast across several time scales. From Pappenberger, F., E. Stephens, J. Thielen, P. Salamon, D. Demeritt, S. J. van Andel, F. Wetterhall, L. Alfieri, 2012: Visualising probabilistic flood forecast information: expert preferences and perceptions of best practice in uncertainty communication. *Hydrol. Process.*, doi: 10.1002/hyp.9253.

5.16.3.1 Environmental and Socioeconomic Change

Climate and its related flooding during prehistorical and early historical times have had a profound impact on human settlement and field abandonment, and consequently cultural adaptation (exchange, collapse, or emergence of new culture). Bonsall et al. (2002) provide evidence to demonstrate the correlation between abandonment of the Stone Age sites in the Iron Gates and a distinct global climatic oscillation between *c.*7250 and 7500 cal BP (calibrated years before present), which was a major flood period along the Danube. Farmers were forced to give up riverbank settlements and explore agricultural potential of other areas. The flooding active period was followed by a quiescent period when reduced flood frequency allowed farming settlements to be established on the formally abandoned sites on the floodplains. Cui and Zhou (2003) present a study on the correlation between floods and cultural adaptation in China approximately 4000 years ago when the climate became colder and major flood events persisted for many years. This period is the so-called 'Great Flood of China, which led to population displacement and establishment of a new integrated Chinese culture in the central plain region in China.' The tendency described above continues, and one of the most significant ongoing environmental changes on the planet today pertains to the massive urbanization process taking place in the developing world. Driven by socioeconomic change on a gargantuan scale (probably never seen on the planet), the rapid creation of new hydromegacities (the term hydromegacity refers to major urban areas or metropolises located near or along large water bodies including rivers, lakes, or lagoons) is unstoppable. According to Bonsall et al. (2002), just 25 years ago, less than 2% of the global population resided in 'megacities' of 10 million or more inhabitants. Today, the proportion exceeds 4%, and by 2015, it will top 5%, when megacities will likely house 400 million people (de Sherbinin et al. 2007).

The level of risk in major coastal cities in these countries will grow because of a combination of the five drivers of risk and vulnerability (DRV). In addition, poor infrastructure, immature emergency response apparatus, the presence of slums, and the absence or infantile nature of exposure and vulnerability mapping methods in spatial planning further acerbate the problem. Hanson et al. (2011) show high population and economic exposure to storm surge and flood risk in many of the world's largest and fastest growing cities. Interestingly, Ranger et al. (2011) report that these are also areas where adaptation can have significant benefits. Both flood risk and vulnerability in the future are explored further in the following subsections. Today the proportion exceeds 4% and by 2015 it will top 5%, when megacities will likely house 400 million people (de Sherbinin et al. 2007). Figure 5 illustrates per country population that are estimated to be exposed to coastal flooding in 2007 and 2070. Of the listed 15 countries, 12 can be described as developing nations.

5.16.3.2 What Is 'Flood Risk?'

We define flooding as the subjection of a particular point location, area, or region to unusually high levels of water, leading to temporary or permanent submersion. Risk, in

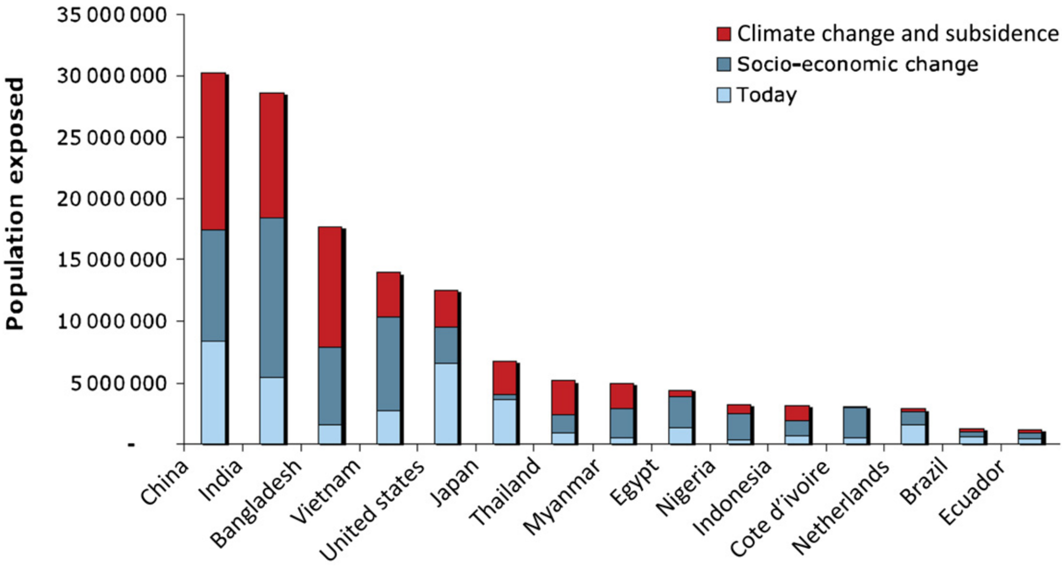

Figure 5 Top 15 countries by population exposed today and in the 2070s, showing the influence of future climate as projected from the IPCC models versus socioeconomic change. Source: Ranking of the world's cities most exposed to coastal flooding today and in the future; OECD press Release, December 2007.

general, can be interpreted as the probability of loss to nature, people, and/or property from a known hazard, as a result of a combination of hazard, exposure, and vulnerability. Flooding can occur anywhere; however, the risk caused by a flood varies in time and space. Variation in time implies that a particular location's propensity to flooding changes with respect to time. For example, flood risk to an art gallery in a city 50 years ago may not be the same today. It might have changed as a result of one or all of the following:

1. Climate variability
2. Landuse change around a nearby retention basin
3. City or urban planning decisions made in the past 50 years

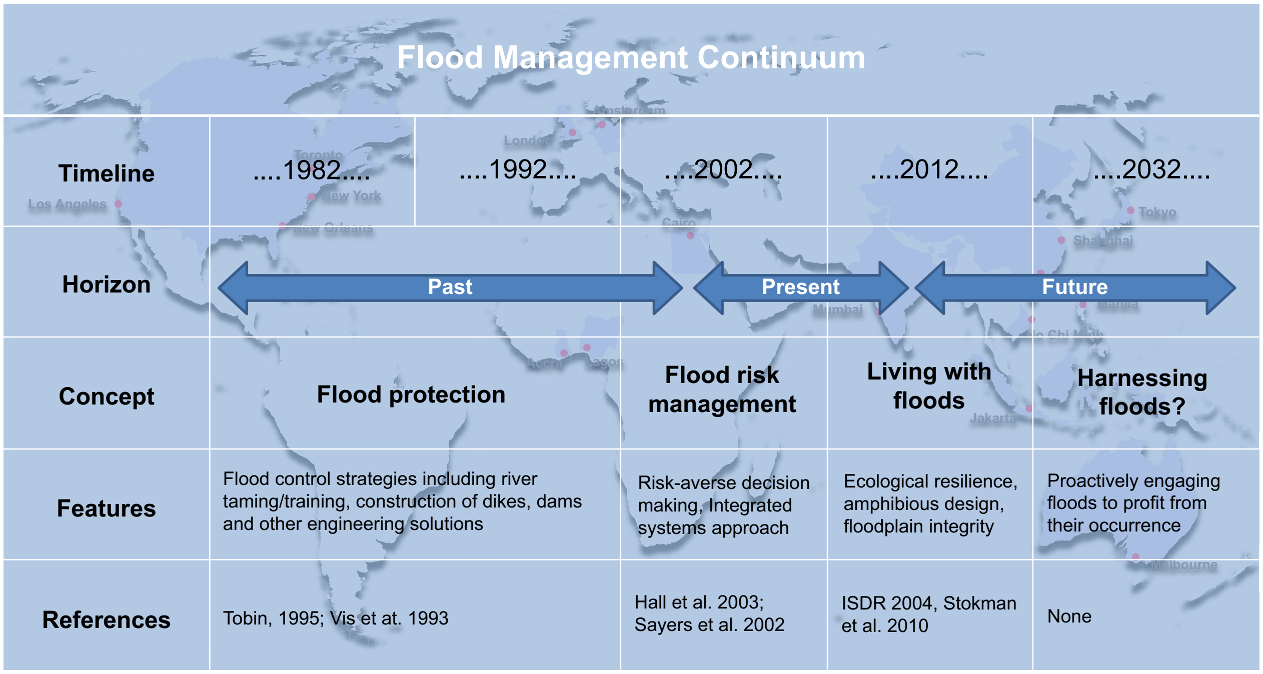
This example practically summarizes the main factors that will affect flood risk and vulnerability in the twenty-first century. Ubiquitous urbanization fueled by population growth and a desire for urban lifestyles, massive landuse change (including record numbers of settlements along coasts, deltas, and estuaries worldwide), and, of course, climate variability will contribute to higher levels of flood risk in the future. These augmented levels of risk will be pronounced in the developing world, where an unprecedented level of population growth and urbanization is currently underway.

There exist several methods to compute flood risk. In this section, we calculate flood risk (F_R) as the probability of flood (F_P) times the consequence of flood (F_C).

$$F_R = F_P \times F_C \qquad [3]$$

Based on eqn [3], one can argue that reducing the flood probability F_P through either engineering interventions (higher dykes or bigger storm drains) or improved forecast lead time can lead to more investment in 'protected' areas, creating a false sense of security and thus increasing the consequences F_C of a potential flood event should 'trusted' defenses fail. The end effect is that although F_P is reduced, should a big flood event breach the reinforced protection, the consequences F_C could be high. In other words, the risk F_R would still be significant (i.e., remain unchanged). This interpretation of eqn [3], which is the norm at present, begs the question: when will our playing catch-up with nature end? For example, if the Q100 (Q100 refers to a 100-year design discharge, that is, a structure designed to handle a flood event that occurs on an average every 100 years) becomes Q50 in 2010 and the Q50 becomes Q5 in 2030, and so on, when does one stop changing his or her design flood, that is, increasing the height of a dyke or the size of a spillway? It is becoming clear that this line of thinking is not sustainable. In other words, given the current knowledge of climate variability and landuse change prognosis, investment in standard human interventions (HI) to *fight* floods might not be the 'smart solution' in the short-term or for the future. We need a paradigm change to concepts that enable us to adapt to new unpredictable flood trends in both space and time. For example, urban design approaches that intelligently accommodate flooding, a concept one might aptly describe as 'living with floods.' We explore this idea in more detail in Section 5.16.3.3 What Is 'Flood Vulnerability?'. **Figure 6**, an evolution of flood management, depicts the change in the perception of flood risk presented as a flood management continuum.

Exploring flood risk would be incomplete without reference to the concept of hazard. According to the *American Planning Association*, a hazard can be defined as "an event or physical condition that has the potential to cause fatalities, injuries, property and infrastructure damage, agricultural loss, harm to the environment, interruption of business, or other types of harm or loss." With reference to the proposed definition of risk, one can surmise that within a specific flood hazard area, there may be similar exposure or risk of flooding but a wide range of vulnerabilities. Most risk quantification approaches follow a standard catastrophe risk modeling framework that combines estimates of hazard, exposure, and vulnerability (Grossi and



Flood Management Continuum

Kunreuther 2005). This leads us to the next subsection, which addresses vulnerability.

5.16.3.3 What Is 'Flood Vulnerability?'

We define vulnerability as the ability to resist or recover from the impact of a hazard in both long and short term. An element or a system can be thought of as vulnerable. Buildings or human beings are types of elements, whereas cities, regions, or economies are examples of systems. We represent vulnerability with the following equation:

$$V = f(S, E, R) \qquad [4]$$

where

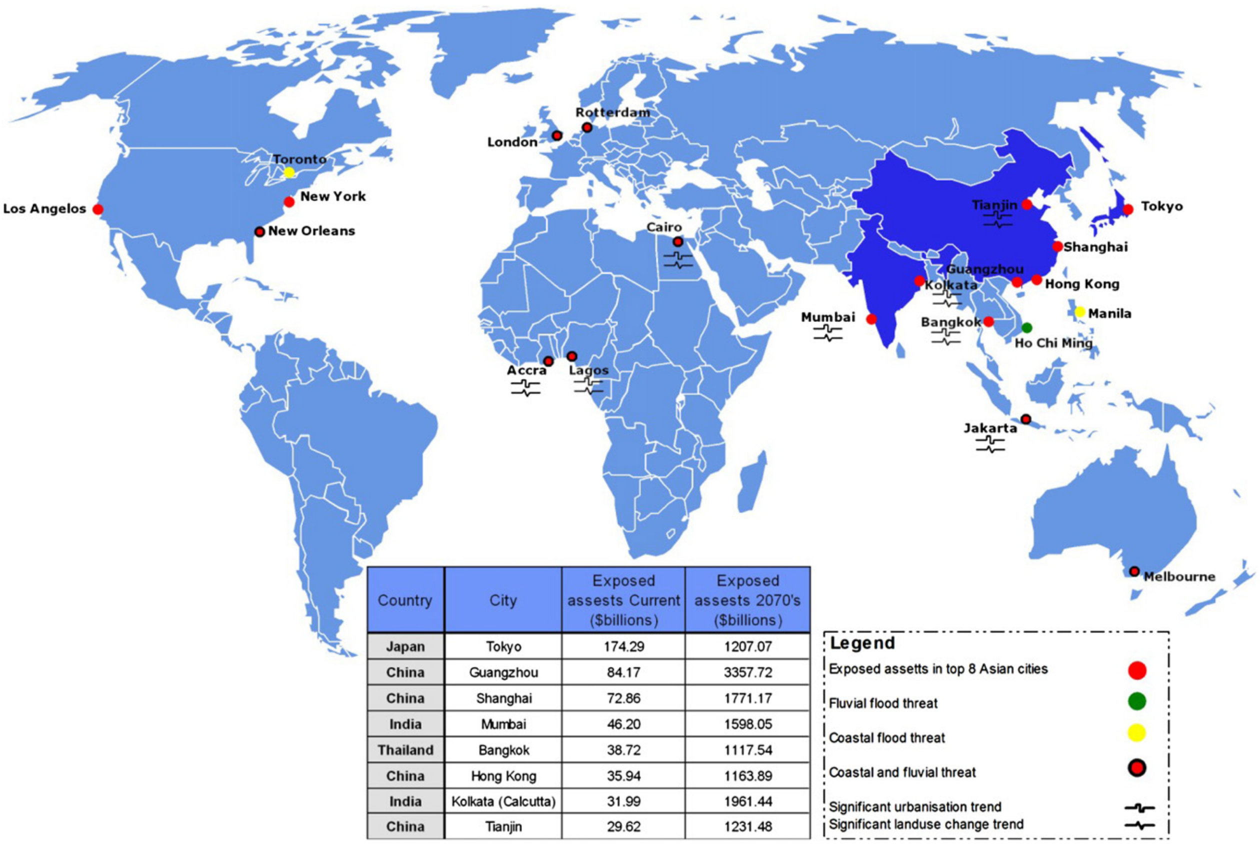
V = vulnerability
S = susceptibility
E = exposure
R = resilience

V depends on many factors including landuse, building design and construction concepts, planning paradigm, forecast skill, effective communication of an impending hazard, and willingness and ability to take responsive actions. Naturally, these factors increase flood risk and also affect vulnerability. Increased unmitigated risk will thus result in high or very high vulnerability, especially under existing paradigms that emphasize increased 'active' HI (higher dikes, better early warning, etc.). Indirect intervention including smart and sustainable urban design or a paradigm shift from 'fighting floods' to 'living with floods' can induce passive resistance to flooding and thus reduce vulnerability. Creating multipurpose infrastructure or waterscapes (Amphibious city landscapes) through amphibious urban design appears to be one of the more promising ways forward, given the current state of affairs.

Both flood risk and vulnerability are important to the insurance and reinsurance industries in which catastrophe modeling is used to determine risk and vulnerability to a range of exposures. Vulnerability, in modeling parlance, can be estimated as the damage cost to a property expected for known water levels expressed in terms of mean damage ratios (monetary damage as a proportion of the total value of an affected property). Benefits of this kind of modeling to an insurer's underwriting strategy cannot be understated. The main output of a probabilistic catastrophe model is the exceedance probability (EP) curve, which illustrates the annual probability of exceeding a certain level of loss (Grossi and TeHennepe 2009). One key risk metric derived from an EP curve is the average annual loss (AAL). AAL is an estimate of the annual premium needed to cover losses from the modeled peril(s) over time, assuming that the exposure remains constant (Grossi and TeHennepe 2009). Figure 7 illustrates global flood vulnerability in coastal and delta cities including the top eight Asian cities in terms of assets exposed to coastal flooding.

5.16.3.4 Resilence—A Paradigm Shift?

Disaster after disaster, we are reminded of the devastating nature of floods. The Mindanao floods on 18 December 2011 in the Philippines claimed over 1100 lives (Agence Presse-France (Philippines floods (December 2011). News item accessed at http://newsinfo.inquirer.net/116107/1000-missing-in-mindanao-floods%E2%80%94government)). The region received a month's worth of rain in just over 3 h. The high death toll was partly because Typhoon Washi hit the southern island in the middle of the night with the worse affected areas being settlements along river banks susceptible to flooding. The storyline is familiar, and, unfortunately, this will not be the last time we



Country	City	Exposed assests Current ($billions)	Exposed assests 2070's ($billions)

hear or read it. The question thus is why this scenario keeps repeating itself the world over. And how can we use current know-how and technology to solve this wicked situation? Naturally, the answer to this question is multifaceted and complicated.

As with most complex issues, it is nearly impossible to have one single solution as an ultimate answer. Resilience is certainly one of the accoutrements in our arsenal in the collective bid to come to grips with the flood menace, worldwide. Building resilience will thus require a multidimensional perspective that combines proven existing methods and novel avant-garde or forward-looking approaches. Resilience is *a state of being* that we can achieve with a set of deliberate steps initiated with a common objective in mind to develop inherent resistance and thus reduce vulnerability to flooding. To attain holistic resilience to flooding, especially in the twenty-first century, we advocate what we term 'living with floods', a form of passive and/or active 'facilitation' of nature's role in minimizing the impacts of floods. Living with floods as a concept per se is not new. However, the version proposed in this chapter goes beyond the conventional view of *living with*, *tolerating*, or *coping with* floods. Figure 8 illustrates the five-element concept composed of two principal components: (1) natural intervention (NI), also known as passive facilitation and (2) HI or active facilitation. 'Living with floods' is a multifaceted approach that inherently engenders resilience.

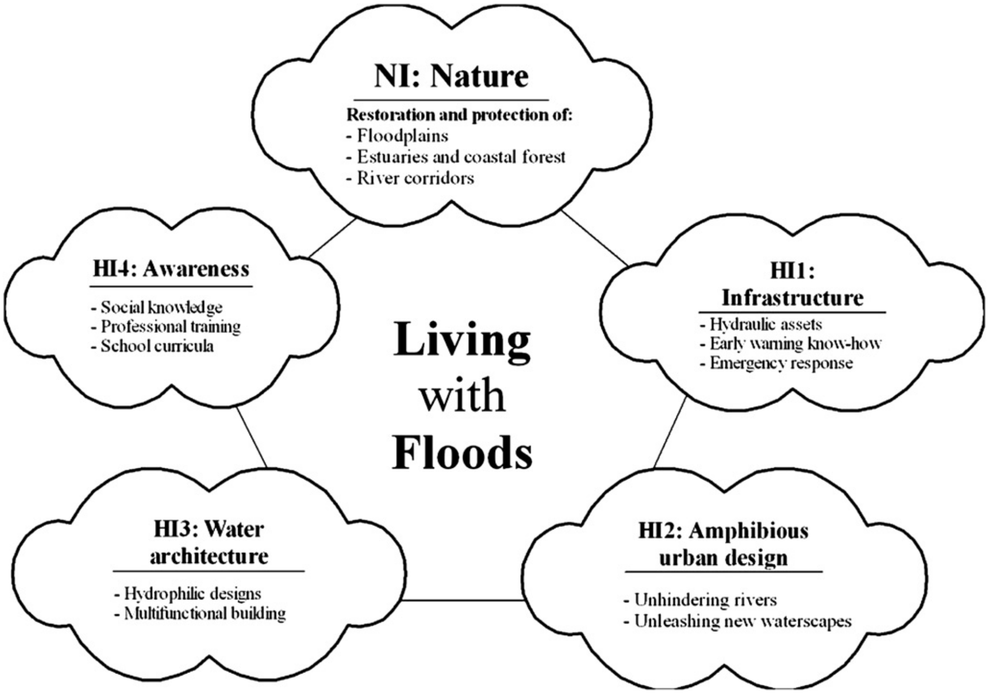
We define NI as a set of activities that *facilitate* the return of modified or engineered floodplains, estuarine landscapes, and/or river corridors to a state equivalent to conditions before human interference. NI is passive, that is, the motive force behind all objectives is the well-being of 'nature.' The mantra here is ultimate respect and priority for nature in all things flood related. HI, on the other hand, refers to activities initiated or devised by human ingenuity to promote a harmonious human cohabitation with nature. HI is active; in other words, the driving force behind all outcomes of the concept is 'human' or anthropogenic. HI is further divided into the following four elements:

1. HI1: Infrastructure
2. HI2: Amphibious urban design
3. HI3: Water architecture
4. HI4: Awareness

The five-element resilience building concept is discussed in further detail in the following subsections.

5.16.3.5 Natural Intervention

NI is the principal focus of the concept 'living with floods.' Here, landscape restoration especially of floodplains, river corridors, estuaries, and deltas is given priority. Not only do these unique systems have to be restored, they also have to be



NI: Nature
Restoration and protection of:
- Floodplains
- Estuaries and coastal forest
- River corridors
HI4: Awareness
- Social knowledge
- Professional training
- School curricula
HI1: Infrastructure
- Hydraulic assets
- Early warning know-how
- Emergency response
Living with Floods
HI3: Water architecture
- Hydrophilic designs
- Multifunctional building
HI2: Amphibious urban design
- Unhindering rivers
- Unleashing new waterscapes

Figure 8 Paradigm shift? Living with floods: a holistic perspective toward achieving resilience (NI, natural intervention; HI, human intervention).

protected, by legislation if necessary, to ensure they are able to deliver requisite ecosystem services and functions.

5.16.3.6 Human Intervention (HI)

Human response to the flood menace is as old as the first encounter between humankind and flooding. Building resilience in society would be better served by deliberate attempts at accessing old cultural flood-proofing habitats that have either been lost or ignored by 'modern' thinking. Sultana (2010) makes the distinction between flood control, which generally emphasizes engineering and infrastructural interventions in managing floods, and *flood coping*, which focuses on the indigenous and socially mediated efforts of people to cope with floods and mitigate its impacts. The concept we advocate, especially the HI component, differs significantly from traditional engineering solutions. All infrastructural and engineering endeavors envisaged within HI, conceptually, are intended to complement nature or ensure that floodplains and river corridors return to preimpacted conditions.

The four elements of the HI component of the proposed concept living with floods are intended to cover the entire spectrum of human-mediated resilience. HI1 infrastructure refers to the use of redesigned hydraulic assets to guide or assist floods to achieve their natural function in the landscape. HI2 and HI3, amphibious urban design and water architecture, respectively, follow a similar logic. They expound a rethinking of urban design and planning to reflect the realities of the flood risk mitigation in the twenty-first century and beyond. HI4 awareness, the fourth and final pillar of the four-element HI component advocates creating awareness. Raising consciousness in civil society, especially in highly vulnerable regions of the world, to current intricate sociophysical dynamics that govern floods, prosperity, and the sanctity of nature is the goal of HI4.

From a cursory glance at the situation, one can easily prognosticate a conflict between human development needs and making room for nature, that is, floods. These two objectives are, however, not mutually exclusive. Figure 9(a) shows new Dutch models of using space that would otherwise be unavailable for habitation. Such approaches are not novel as one might think. Figure 9(b) depicts the 400-year-old floating village of Ganvie in Benin, West Africa. Inhabitants of the village a long time ago decided to change their approach to the design and construction of their dwellings to accommodate persistent or permanent flooding witnessed by their forefathers. Is this a form of resilience? Perhaps, in any case, their approach, along with the Dutch 'Paalwoningen' concept, demonstrates the viability of successful coexistence with floods. One could up the ante and suggest the need to develop ideas and concepts that can essentially profit or benefit from the occurrence of floods!

5.16.4 Concluding Remarks

The previous three sections have demonstrated the complexity of a growing flood menace. The competing risks and vulnerabilities stemming from population growth (especially in developing countries), urbanization, landuse change, and climate variability and longer-term change produce a very intricate picture of what effects future flooding might have. The first section makes a clear connection between present trends in environmental change and their potential impacts on floods. Be it urbanization affecting radiative forcing or alteration of catchment characteristics, we know they can only worsen the

impact of floods. The second section dwells on inundation assessment through standard methods such as 2D hydraulic modeling. The lesson here, it appears, is the relative lower levels of uncertainty introduced by inundation modeling as compared to other parts of the flood modeling cascade, in particular, climate prediction. It limits our ability in making reliable statements on the impact of the climate on flood inundation. The fact that future climate input for flood inundation modeling is driven mainly by highly uncertain GCM/RCM output reduces all attempts at forecasting inundation levels in the near and distant future to almost guesswork. The third section assesses the changing nature of flood risk and vulnerability especially in the developing world. It presents the evolution of flood management over the past and proposes the concept of 'harnessing floods' that potentially engenders resilience while advocating working with nature, not against it.

Many of the trends identified in the chapter such as population growth and urbanization, including the creation of megahydrocities, cannot be stopped. To deal with these challenges, it would require ingenuity and new engineering know-how. At the end of the flood management continuum presented in Figure 6, the issue of harnessing the power of floods is mooted. Is this wishful thinking or real engineering goals for the future? Solutions already exist that begin to hint at such thinking. The 'Stormwater Management and Road Tunnel' or 'SMART Tunnel' in Kuala Lumpur (http://www.smarttunnel.com.my/), Malaysia, is an example of multifunctional design that combines storm water control with traffic management. On the forecast front, although there are huge uncertainties in our abilities to characterize and model future floods, progress continues to be made in climate modeling.

The findings in this chapter show that to manage future flood risk sustainably, a portfolio of integrated concepts, measures, and avant-garde thinking would be required.

5.17.1 Introduction: Climate and Vulnerability in the Netherlands

The Netherlands is a low-lying country in the delta of the Rhine and Meuse rivers, which discharge water from the Alpine and Ardennes highlands in Western Europe toward the North Sea. Throughout the centuries this delta position has created considerable opportunities for socioeconomic development, owing to the sedimentation of fertile land, the use of the rivers for trade and transportation, fresh water availability for agriculture, etc. But the delta environment has also introduced pronounced challenges for the population to adapt to rapidly fluctuating and changing natural conditions, and to protect from hazards such as storms, floods, and droughts.

From the second half of the past century a number of such hazards have strongly shaped the physical and socioeconomic infrastructure of the country. A major flooding from a strong sea surge and storm in 1953 with over 1800 casualties gave rise to the First Delta Programme, which resulted in major coastal defense systems including the sophisticated Oosterschelde and Maeslant barrier constructions. A near flooding of the Rhine River in 1995 and prolonged drought conditions in 1976 and 2003 increased the awareness that also the fresh water supply from the upstream catchment area is subject to strong temporal variability, which needs to be coped with. The Second Delta Committee completed their report in 2008 (Delta Committee 2008), pointing at the need to reconsider the safety levels and design of the defense system both for coastal protection and river management, in order to be prepared for the trends in climate and socioeconomic development that are ongoing and projected.

The awareness of the vulnerable position of the country in a low-lying delta (26% of the Netherlands is below sea level) in general, and the Delta Programmes specifically, have triggered a considerable volume of scientific research in the area of climate variability, hydrological variability, hydraulic engineering, decision support systems, cost–benefit analyses, water use, risk perception, spatial planning, and interactions between all these disciplines and sectors. Since the mid-1990s intensive collaboration exists between Dutch research institutes involved in water management and weather/climate, leading to a suite of projections for impact assessment studies of the Dutch major hydrological systems (e.g., Kwadijk and Rotmans 1995), first-order assessments of climate and possible changes in the frequency of extreme events at the national level (Können 2001), software tools for extreme value statistics (Buishand and Leander 2011), and coupling between meteorological and hydrological/wave models (FEWS 2011). More comprehensive research programs were developed in the early 2000s, in particular the Dutch National Program on Global Air Pollution and Climate Change (NRP; Berdowski et al. 2011), Climate Changes Spatial Planning program (CCSP 2011) (2004–11), and the Knowledge for Climate program (KfC 2011) (2007–13). CCSP was designed as a multidisciplinary research program focusing on the development of climate scenarios, land use-related mitigation options, sector-specific adaptation projects, and cross-cutting cost–benefit analysis and spatial planning projects. It paved the way for further analysis of climate adaptation options for a number of vulnerable 'hotspots' in the Netherlands, including the Rotterdam harbor, Schiphol airport, the rural peatland and sand areas, and the coastal/river defense systems in KfC. In addition, the Second Delta Committee report focused on a limited number of vulnerable hotspot areas where either the chance for occurrence of extreme disrupting events or the socioeconomic consequences of such events were contributing to a high risk level. Research supporting this influential Delta Committee report relied heavily on the lively multidisciplinary research networks that were created by the CCSP and KfC programs.

Traditionally, the systems for water management and other infrastructure have been designed under the assumption that climate is stationary (Klein Tank et al. 2009). New infrastructure is typically designed on the basis of historical information on weather and climate extremes, where the maximum value of a particular variable in the historical record is considered to be the normative value for design. In other cases, extreme value theory has been applied to the historical observations of extremes to estimate the normative value, again disregarding

changes in the climate statistics. The notion of the mean, variability, and extremes of relevant weather variables is now widely accepted. Recent adaptation strategies begin to account for the changes in extremes observed in the past decades, as well as projections of future changes in extremes such as are obtained from climate models. Some types of infrastructure currently have little margin to buffer the impacts of changes in climate statistics. A recent evaluation (Ten Brinke et al. 2008) indicates that at least 15% of the primary dike system in the Netherlands does not meet the safety standards as set down in Dutch national law because of increasing sea height extremes associated with rising sea levels. In other cases, projected changes (although highly uncertain) are so large that simply relying on traditional adaptation methods would no longer appear to be prudent.

To guide this process, the Royal Netherlands Meteorological Institute (KNMI) developed a set of climate change scenarios, containing indicators of changes in the mean and extremes of a number of relevant climate variables, relative to a reference period (KNMI'06, Van den Hurk et al. 2007). In this chapter, the terminology 'climate change' refers to changes in climate statistics over multidecadal time scales. Although the construction of KNMI'06 follows a typical top–down information chain approach (from the Intergovernmental Panel on Climate Change (IPCC) Special Report on Emissions Scenarios (SRES) to a range of climate projections to a set of downscaling steps to a statistical post-processing at the local level using observations to a variety of sector-specific impact assessment tools, leading possibly to an appropriate response), the scenarios have been designed to serve as a benchmark for bottom–up application in different sectors in which vulnerable hotspots are taken as a starting point with the eventual goal to derive adaptation strategies. This bottom–up procedure (also addressed as 'adaptation tipping point analysis'; Kwadijk et al. 2010) essentially follows a reversed chain of analysis: after defining potential impacts that need to be avoided or mitigated, an assessment of the corresponding climate characteristics that lead to these impacts is made. Comparison with climate projections is applied to determine whether/when these conditions can be expected.

This chapter discusses a number of recent Dutch case studies against the background of the seven key guideline questions corresponding to a vulnerability-based assessment (Wilby and Dessai 2010; Pielke et al., in press). In these case studies, both climate and socioeconomic drivers play a role. In each of these case studies the vulnerability aspects will be reviewed, the impact of climate on these aspects will be assessed, and a discussion of the communication of climate change information by means of a discrete set of scenarios will be included. After these (bottom–up defined) case studies, a brief description of the construction and rationale behind the (top–down oriented) KNMI'06 scenarios will be described. Particularly, the confluence of the top–down and bottom–up approaches is illustrated by examining the role of the scenarios as a benchmark in these and other vulnerability assessment studies, and the stakeholder involvement in their design and update. The chapter concludes with a general assessment of the degree to which the climate change scenarios have been helpful for adaptation in the Netherlands.

5.17.2 Case Studies in the Context of Vulnerability Assessment

According to Pielke et al. (in press), a bottom–up analysis of vulnerable resources should be built around seven key questions:

1. Why is this resource important? How is it used? To which stakeholders is it valuable?
2. What are the key environmental and social variables that influence this resource?
3. What is the sensitivity of this resource to changes in each of these key variables? (This may include, but is not limited to, the sensitivity of the resource to climate variations and change on short (days), medium (seasons), and long (multidecadal) time scales).
4. What changes (thresholds) in these key variables would have to occur to result in a negative (or positive) outcome for this resource?
5. What are the best estimates of the probabilities for these changes to occur? What tools are available to quantify the effect of these changes? Can these estimates be skillfully predicted?
6. What actions (adaptation/mitigation) can be undertaken in order to minimize or eliminate the negative consequences of these changes (or to optimize a positive response)?
7. What are the specific recommendations for policy makers and other stakeholders?

To provide a motivation for each of the case studies (described in more detail in the following subsections), these questions have been addressed briefly as summarized in **Table 1**.

The first case study (Te Linde et al. 2011) describes a climate and socioeconomic scenario assessment for the Rhine area. The flood-prone areas near the riverbanks are protected by a mixed set of safety measures for a given design river discharge. For this particular area, the stakeholder population is quite broad: in fact, all socioeconomic factors in the flood-prone area are to be considered. Apart from changes in climate-related discharge regimes, increasing concentrations of socioeconomic value in the riparian areas are changing drivers, leading to a necessary reassessment of the current design discharge. This design discharge can be changed by infrastructural measures, in combination with exploration of revisiting disaster policies, financial arrangements, and liability structures, such as recommended by the Second Delta Committee.

A second case study describes the coastal defense strategy analyzed in detail by the Second Delta Committee. As for the Rhine area, a storm surge defense infrastructure is constructed based on rare extreme surge levels with a predefined (design) return time. This case study also assigns a wide range of stakeholders, owing to the high socioeconomic value located in the Dutch coastal area. Critical drivers and thresholds are determined by both climatological sea level and associated storm surge regimes, and socioeconomic pressure on the area. An expert evaluation of possible sea level change during the twenty-first century has resulted in a range of values, of which the upper value is of higher relevance than the low end of the range, because of the asymmetric socioeconomic implications. Migration of the population away from the area below sea level is far less feasible than adopting sophisticated flood protection

Table 1 Overview of key questions of vulnerability assessment for the case studies

		Case studies		
No	*Question*	*Rhine discharge*	*Coastal defense*	*Extreme precipitation*
1	Why/for whom is resource important?	Everybody. Densely populated area, large socioeconomic value	Everybody. Densely populated area, large socioeconomic value	Urban water management. Regional water management. Emphasis on coastal areas
2	Key environmental and socioeconomic variables	High discharge. High concentration of socioeconomic value along river banks	Extreme storm surge. High concentration of socioeconomic value along coast	Extreme precipitation. Land use
3	Sensitivity of resource to change in key variable	Increases in high discharge and socioeconomic value both increase risk for damage	Increases in storm surge risk and socioeconomic value both increase risk for damage	Higher extremes and more intense land use (urbanization) lead to more damage
4	Thresholds leading to positive/negative response	Present norm: 16 000 $m^3\ s^{-1}$, based on somewhat arbitrary assessment of ‘acceptable risk for damage’	Present norm: 1/10 000 years, based on somewhat arbitrary assessment of ‘acceptable risk’ (a 1% chance for a major flooding per century)	Urban areas: sewage design should withstand 1/10 years showers. Polder areas should flood less often than once per year
5	Best estimates of probabilities of thresholds to occur	For both drivers: dependent on chosen scenario. Scenarios reflect uncertainty in future developments	Storm surge: expert judgment says 60–120 cm by 2100. Only upper value of this range is ‘politically relevant’	Inland showers: intensity scales with temperature change. Coastal heavy rain: change of North Sea temperature is a driver. Land use: urbanization will increase
6	What adapation/mitigation actions?	Flood protection measures. Increasing design discharge	Stronger coastal defense. Moving away socioeconomic value from coastal area is for the time being not an option	Bigger sewage systems/pumping systems. Water retention integrated in landscape
7	Recommendations for policy makers	Follow Delta Committee recommendations	Follow Delta Committee recommendations and apply adaptive management (monitoring actual sea level rise)	Increase resilience by technology

as an adaptation measure. The Delta Committee recommended applying 'adaptive management' here and keeping the coastal defense system in line with updated information on sea level rise (SLR) and socioeconomic developments.

A final case study is included here to illustrate the role of climate change scenarios as a picture of possible future conditions, rather than as predictive tools. The summer of 2006 was characterized by a very hot July followed by a very wet August, leading to severe flooding in some urban areas near the North Sea coast. These extreme precipitation aspects also have a mixed set of stakeholders. Waterboards are responsible for water management in the rural and urban areas, but response measures in the rural area (pumping capacity, (ground) water management) differ from infrastructural measures (sewage design) in the urban areas. Climatic drivers behind changes in extreme precipitation levels vary across the country, where the North Sea exerts a clear influence on the coastal area. Increasing resilience by technological measures is one of the most straightforward adaptation measures.

5.17.3 Protection against River Floods in the Rhine Basin

The Rhine is a mixed rainfall/snowmelt river with a mean discharge regime that shows a relatively small annual cycle with a maximum in late spring and a multiyear mean of approximately 2300 $m^3\ s^{-1}$. Flooding events are governed by multiday episodes of widespread rainfall across the 160 000-km^2 large basin, excessive snow melt from Germany and the Alpine area in response to high temperatures in spring, or a combination of these (Te Linde et al. 2011). Estimates of the 1/1250-year return level based on extreme value statistics using historic discharge records result in a value of 16 000 $m^3\ s^{-1}$ as the current design discharge for the majority of river bank areas in the Netherlands.

The Rhine Delta is a densely populated area. Over the past century the historic discharge time series has been affected by upstream infrastructure measures (dikes, straightening stretches for shipping, retention areas) and water management (e.g., lake level control in Switzerland). Urbanization and concentration of capital in major industry areas has increased the economic and societal value of the area along the river that is prone to flooding (Klijn et al. 2004). The ongoing concentration of socioeconomic value along the riverbanks together with changes in the discharge regime induced by climate and infrastructural developments has increased the need to reassess the acceptable flood risk, as noted by the Second Delta Committee.

Many studies have been conducted addressing the implications of changing climate statistics for the extreme discharge regime of the Rhine. These were pioneered by the study of Kwadijk and Rotmans (1995), who showed that the seasonality of the mean discharge regime shifts from a mixed rain/snowmelt river toward a rainfall-dominated system under warming conditions. Increases in projected winter precipitation leads to increases in the design discharge, and multiple studies using different approaches have confirmed this increase, with a range of design discharge increases between roughly 1000 and 3000 $m^3\,s^{-1}$ for the year 2100 (Shabalova and van Deursen 2003; Lenderink et al. 2007b; Ward et al. in press).

However, the vulnerability of the riparian area is affected not only by changes in the climate-driven peak discharge but also by the potential damage caused by a flooding event. In the context of the Delta Committee assessment and the CCSP research program, Te Linde et al. (2011) and Ward et al. (in press) explicitly included this nonclimatic aspect of vulnerability changes in their studies of anticipated changes in the flood risk for the Rhine area.

Te Linde et al. (2011) analyzed the present and future flood risks for a number of areal stretches along the main branch of the Rhine River (**Figure 1(a)**). Flood risk is here the product of the annual probability of flooding in a given area and the expected damage when flooding occurs. The estimates are based on a modeling chain involving historic climate data (precipitation and temperature), hydrological processes, hydraulic flooding, and an economic loss model driven by inundation depths. For a limited number of climate scenarios, protection measures, and land-use scenarios up to 2030, changes in this flood risk are calculated. The land-use scenarios are socioeconomic translations of the regional distribution of economical value in the riparian areas in response to large-scale socioeconomic drivers, leading to an increase in the property value in the area of interest. The two climate change scenarios used in this study were constructed from very different approaches, but both led to a substantial change in the precipitation regime relevant for flood occurrence. This approach is not intended to cover a specific uncertainty range in future climate conditions, but merely illustrates the sensitivity of flood risk to changing climate statistics over a hypothetical range of conditions. In total, six scenario calculations were conducted: two climate change scenarios, two land-use scenarios, and two situations where both were applied (combining a smaller or larger climate change signal with a smaller or larger land-use change projection, respectively). In this set-up the flood risk increased in all scenarios, and the climate signal dominated the land-use signal (**Figure 1(b)**). However, the simulations with both high-end scenarios combined resulted in a larger increase in the flood risk than the summation of the two separate climate/land-use scenarios. Thus, the damage due to the change of one acting agent depends on the change of the other acting agent. A straightforward interpretation of this finding is that for a stronger increase in the socioeconomic value in a flooded area the risk effect for a given event is larger.

A later study by Ward et al. (in press) elaborates on this using a probabilistic framework. In their approach, a similar modeling chain was set up, but a larger sample of climate change scenarios was processed, derived from downscaled data sets from 12 Global Climate Models (GCMs) used for the fourth IPCC assessment report (AR4) (Van Pelt et al. submitted). Apart from a general confirmation of the findings of Te Linde et al. (2011) this study illustrated the use of a wide sample of scenario projections to compute the probability for a given damage to occur. Acknowledging methodological limitations they used their probabilistic sample and estimated the probability of the high flood damage scenario shown by Te Linde et al. (2011) to be between <0.1 and 11%, depending on the specific target area.

Figure 1 Summary of the analysis of Te Linde, A. H., P. Bubeck, J. E. C. Dekkers, H. de Moel, and J. C. J. H. Aerts, 2011: Future flood risk estimates along the river Rhine. *Nat. Hazards Earth Syst. Sci.*, **11**, 459–473, http://dx.doi.org/10.5194/nhess-11-459-2011. (a) Current (reference year 2000) flood risk expressed in million euros per year for a number of riparian areas along the main Rhine branch. (b) Total risk in the investigated areas for the reference year and for 2030 for two climate and socioeconomic scenarios. The low/high climate change scenarios The label "RACMO" represents a low scenario, while "Wp" represent a high scenario are combined with the low/high land-use change scenarios (low: RC; high: GE), respectively (see text).

Both studies stress the limited scope of their analyses, and present their results for illustration and methodological demonstration purposes only. Here it needs to be emphasized that the quantitative results of these studies are not to be considered as a representative estimate of scenario-specific future conditions for the flood damage in the Rhine area. However, the studies do illustrate clearly that a nonlinear response of socioeconomic developments and climate exists at the regional spatial scale at which vulnerability assessments normally are applied. They do demonstrate the need to incorporate nonclimatic scenarios or other forms of uncertainty mapping (Bubeck et al. 2011), and call for a continued and reinforced cooperation between the relevant disciplines involved.

5.17.4 Coastal Defense: Storm Surges and Sea Level Rise

As discussed earlier, the Netherlands is subject to large fluctuations in the physical environment. Historically, frequent floods not only shaped the country but also gave rise to the design of a robust flood defense system, both from coastal and riverine directions. The coastal defense and water sectors were early adapters to climate.

The first major Delta Programme, completed a decade ago, is designed to reduce the probability of occurrence of events similar to the Zeeland flooding in 1953 to once per 10 000 years in regions of high economic value, down to once

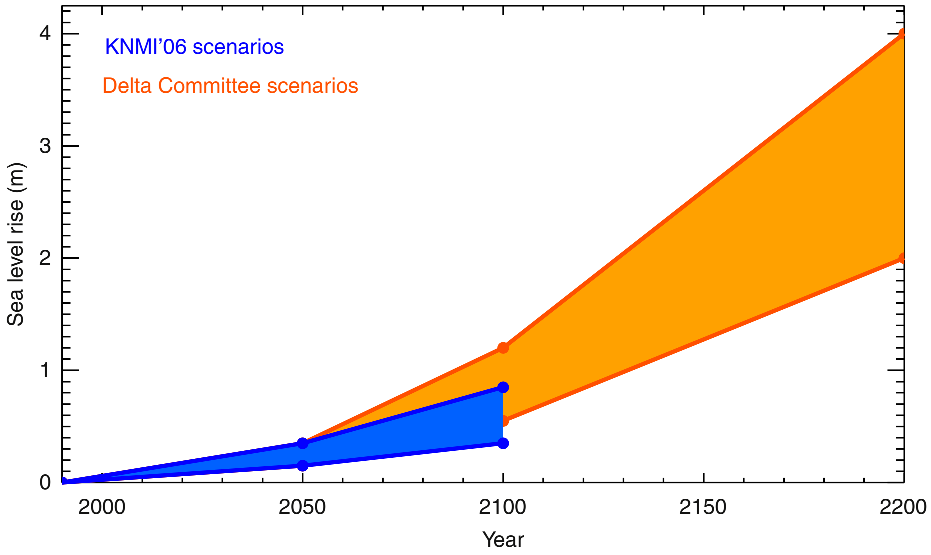

Figure 2 Scenarios of sea level rise from KNMI'06 (blue) and from the Delta Committee (orange). Vellinga, P., C. A. Katsman, A. Sterl, and J. J. Beersma, Eds., 23/11/2009: *Exploring high-end climate change scenarios for flood protection of the Netherlands. International Scientific Assessment carried out at the request of the Delta Committee*. KNMI publication: WR-2009-05, [Available online at http://www.knmi.nl/bibliotheek/knmipubWR/WR2009-05.pdf]

per 1250 years elsewhere. This return level, the so-called safety standard, is not objectively based on economic cost/loss calculations, but reflects the major society concern of exposure to such devastating events. Changes in climate statistics, or the related SLR, was not considered in this First Delta Programme: the calculations of the water levels with a return time of 10 000 years used to design coastal and riverine defense structures were based on statistical extrapolation of observed and modeled sea level fluctuations of the past, assuming a stationary mean climate.

Since the second half of the twentieth century, the situation has changed. Changes in climate statistics are now an issue of concern in this low-lying delta. In addition, increased value of the society capital protected by the flood defense systems has given rise to reconsider the 1/10 000 years safety standard. The Second Delta Committee (2008) resulted in a scientific reassessment of the Dutch coastal defense system. This reassessment comprised both an evaluation of SLR and updated modeling capacity for storm surge projections (Sterl et al. 2009; Van den Brink et al. 2004). Here, the evaluation of SLR has been discussed in detail.

The KNMI'06 climate change scenarios include estimates of the projected mean SLR at the Dutch coast for different global mean temperature scenarios, leading to values between +35 and +85 cm in 2100 relative to 1990. Following AR4, the Second Delta Committee realized that sea level scenarios are subject to considerable uncertainty, including the role of major ice sheets, global mean temperature rise, paleoreconstructions on rates of global mean sea level change, and previously underrepresented mechanisms such as gravitational effects of ice sheet changes and ground water extraction. As a result, the range of SLR that should be taken into account for coastal defense may be much wider than represented by KNMI'06. A semiobjective procedure was followed by asking an international team of experts to provide a consensus assessment of the plausible high-end sea level change in 2100 and beyond, incorporating the multiple uncertainties associated with this estimate. This committee (Vellinga et al. 2009; Katsman et al. 2011) provided a range of high-end sea level changes between +55 and +120 cm (excluding effects of local surface subsidence), which is different from reporting on the full range of possible SLR scenarios (Figure 2). This difference in assignment explains the difference in the sea level scenario values relative to KNMI'06.

The Delta Committee emphasized the gradual evolution of SLR over time and recommended an adaptive approach, updating measures frequently considering the actual SLR taking place. In all written communications about these sea level scenarios the full range of this assessment (+55 to +120 cm) is used. However, in some political debates in and around the Dutch Parliament, and in some newspaper releases, the Delta Committee tended to emphasize the high end of this scenario range (+120 cm), without giving adequate credit to the reported range of scenarios as perceived by the team of experts. It clearly reflects the differences between scientific and political perspectives of this uncertainty range. The scientific desire to communicate an objective (wide) uncertainty range is not always compatible with the political need to create a sense of urgency.

5.17.5 Extreme Precipitation in the Coastal Area

A high-impact quantity is the occurrence of extreme precipitation, both at the local scale (heavy showers leading to sewage problems, flash floods, construction damage) and at a more widespread regional scale (affecting peak discharge of major rivers or water management problems in watersheds). But the events of extreme precipitation in Western Europe are very episodic and erratic, with low predictability, low consistency, and weak links to nearby or remote drivers.

The concept of climate scenarios is frequently challenged by historic sequences of weather episodes, including the occurrence of extreme precipitation. The summer scenarios of KNMI'06 discern between a relatively dry climate in response to an increase in prevailing easterly winds (with lower wet day frequency and small increases of extreme precipitation) and a warming response without changes in the prevailing wind directions, which is associated with a low change in the wet day frequency but a strong increase in the extreme precipitation level (here defined as the 1/10 year wettest day). Summer 2006 in the Netherlands is remembered by a warm, sunny, and dry July, followed by a very wet August, particularly in the coastal areas that were affected by the high North Sea surface temperature following the warm July episode (Lenderink et al. 2008). One could associate July 2006 with the dry/warm scenario, and August 2006 by the wet/warm scenario. This interpretation violates the nature of scenarios as being illustrative for multiyear climate conditions in which dry and wet episodes both do occur but with different frequencies, yet it also provides a recognizable iconic image for these particular scenarios. In addition, it illustrates the fact that true weather does not follow human-defined scenario pathways, but essentially consists of a superposition of considerable natural variability upon a relatively small change in the mean state. Lenderink et al. (2009) reported on this Summer 2006 event by analyzing the impact of the anomalously high North Sea temperature on the coastal precipitation, providing useful guidance of the KNMI'06 climate change scenarios.

5.17.6 Climate Change Assessments in the Netherlands

The KNMI'06 climate change scenarios (Box 1) allowed a range of society sectors to assess the implications of possible changes in the local climate statistics for their particular applications. For many stakeholders the notion of 'climate change' is related to the time scales that are relevant to a particular application. For example, for the engineers involved in the design of sewer systems with a typical life span of 50 years, changes in climate statistics used for their design criteria (often the historical 50-year period) are referred to as 'climate change.'

The four scenarios emphasize the location of the Dutch delta in a transition zone: in Northern Europe a pronounced increase in wintertime precipitation is projected, whereas the decrease in summertime precipitation is a prominent feature in most future climate projections in Southern Europe. Aspects of both features appear in the four scenarios for the Netherlands. The uncertainty in the signature of this change in the transition zone is also reflected in the strong interannual variability of contemporary seasonal precipitation and temperature in the Netherlands, highly depending on predominant atmospheric circulation conditions.

The KNMI'06 Climate Change Scenarios and Their Updates

The KNMI'06 climate change scenarios for the Netherlands (Van den Hurk et al. 2007) replaced the older Können (2001) scenarios. KNMI'06 was based on an integrated assessment of state-of-the-art climate projections from Global Climate Model (GCM) simulations prepared for the fourth IPCC assessment report (AR4), downscaled data from a suite of Regional Climate Model runs (RCMs; Jacob et al. 2007) and local observations, and regionalization of the IPCC sea level scenarios (Katsman et al. 2010). The ultimate product of KNMI'06 consisted of four descriptive pictures of future climate in the Netherlands expressed as sets of change factors for a number of relevant seasonal meteorological variables (temperature, precipitation, potential evaporation, and wind) for different statistical moments (allowing changes in the mean to be different from changes in extremes). The four sets (or scenarios) were designed to span a fair amount (roughly 80%) of model-based uncertainty in global temperature change and the regional expression of that global change (Lenderink et al. 2007a).

Preparations for a next set of climate change scenarios are currently underway (with the working title 'KNMInext'), driven by a mix of new or updated stakeholder requests (see main text) and progress in the scientific insights and available tools. KNMInext will further develop the concept of 'Future Weather' (Hazeleger et al. submitted), where high-resolution, high-quality, specifically targeted simulations will be used as a virtual laboratory for future weather, with all its spatial and temporal modes of variability that are relevant for the application at hand. The case study of the Dutch North Sea in Summer 2006 is an illustrative example of such a targeted simulation. Simultaneously, tools are being developed to analyze observed anomalous episodes in the context of changes in climate statistics (Stott et al. 2011). The call for this attribution becomes louder: are these events an expression of systematic changes in the frequency of different weather patterns and can we expect more of this to come, or is natural variability the main cause and can current adaptation policy be considered adequate?

KNMI'06 served a wide range of sectors vulnerable to summer droughts (rainfed agriculture, nature conservation, cooling demands for power plants, and soil salinification in the coastal area), seasonal floods (coastal and river defense systems, sewage design in urban areas, and land accessibility for agricultural management), and wind/storm climate (coastal defense, wind energy, and air traffic). For each of these sectors, pilot studies or hotspot analyses were driven with KNMI'06 scenarios as boundary condition, and different (or sometimes additional) scenarios were chosen by different sectors because of a variety in climate regimes to which vulnerability exists (see the coastal defense case study for an example). The climate variables included in the KNMI'06 scenarios were also chosen in close cooperation with stakeholders in the vulnerable sectors: high discharge levels in the Rhine are driven by multiday precipitation extremes, while single-day or even single-event precipitation extremes are boundary conditions for sewage design in urban areas and water table management at polder level. KNMI'06 got a legal status in the National Water Plan (NWP 2011), where timing and target safety levels of maintenance and new developments of the national and regional water systems are regulated between the national and local governments. In addition, the Second Delta Committee assessment and many other sector-specific applications use KNMI'06 as a reference. The development of the scenarios and the incorporation of state-of-the-art model projections have received attention from among others Belgium (that contracted KNMI to produce a similar set of scenarios for their territory), and resembles aspects of the approach followed in other countries such as Australia (CSIRO 2007; Whetton et al. 2012) and Switzerland (OCCC 2007).

The extensive use of KNMI'06 also revealed some shortcomings, many of which have been communicated by users of the scenarios. For instance, it does not contain spatially explicit climate change information. This is unrealistic when considering the considerable climatological gradient across the large Rhine Basin (where changes in the Alpine snow regime will have a different seasonal signature than the projected rainfall changes in the lower parts of the basin). However, at a smaller spatial scale a gradient in the changes in climate statistics is evident. Coastal areas are exposed to considerably higher rainfall rates during warm North Sea conditions in late summer (see earlier).

Another add-on request to KNMI'06 was the exploration of subdaily precipitation extremes, which is a high-impact quantity (leading to sewage problems, flash floods, and construction damage). In particular, the urban environment is very sensitive to short-duration precipitation extremes. Analyzing a large data set of observed hourly precipitation both in De Bilt and in Hong Kong, Lenderink and Van Meijgaard (2008) concluded that the dependence of rare heavy precipitation events on surface dew-point temperature turned out to be much stronger than generally obtained in regional (and global) climate model simulations (Figure 3). Other examples of 'relevant scientific progress' since the release of KNMI'06 exist (such as the analysis of observed temperature trends over western Europe by van Oldenborgh et al. (2009) and the contribution of changes in the gravitational balance by ice sheets to regional SLR by Katsman et al. (2011)). An update of KNMI'06 was published in 2009 (KNMI 2009), where additional guidance to the interpretation of the scenarios was given without a significant alteration of the scenario values themselves.

The Second Delta Programme, launched after the recent advice from the Delta Committee, has generated a set of 'Delta scenarios,' of which changing climate statistics is one of the drivers. Major additional inputs are provided from anticipated changes in land use and socioeconomic key factors such as agriculture, urbanization, economic growth, and property values (Bruggeman et al. 2011). An essential component of these scenarios is a consistent storyline, in which society and environmental developments are pictured in a common framework. In storylines in which economic growth is anticipated to be large, adverse climate effects can be mitigated more easily than for low economic growth rates. Vice versa, the economic growth rate in the Netherlands is a projection of the global economy, and thus the association between economic growth and greenhouse gas emissions (and a climate response to this) should be considered.

These and other developments illustrate the dynamic scientific and policy arena in which climate information is used, updated, and refined.

5.17.7 Concluding Remarks

An important and ongoing discussion addresses the basic intended objective and relevance of (climate change) scenarios (Pielke et al. in press; Wilby and Dessai 2010). One may consider the ensemble of scenarios as a subset of uncertainty in future climate conditions, and the ensemble should be preferably constructed in a way such that a wide range of sources of uncertainties is covered, which are meaningful to the application considered. Alternatively, one may hypothesize that every scenario is a (relevant) case study that is consistent with a given direction of future (climate/socioeconomic) developments, and is adequate for testing a planned adaptation measure under realistic conditions. KNMI'06 scenarios allow both forms of application. For instance, in the context of the Second Delta Programme mentioned earlier, the scenarios are used on one hand to make a selection of proposed adaptation measures, where no regret is a fundamental criterion. In the second instance, they will be used to confront the selected measures using a realistic set of future environmental and socioeconomic conditions, for which a high level of realism is mandatory. The dual perspective of climate information illustrates the need to close the gap between (top–down) climate model-derived

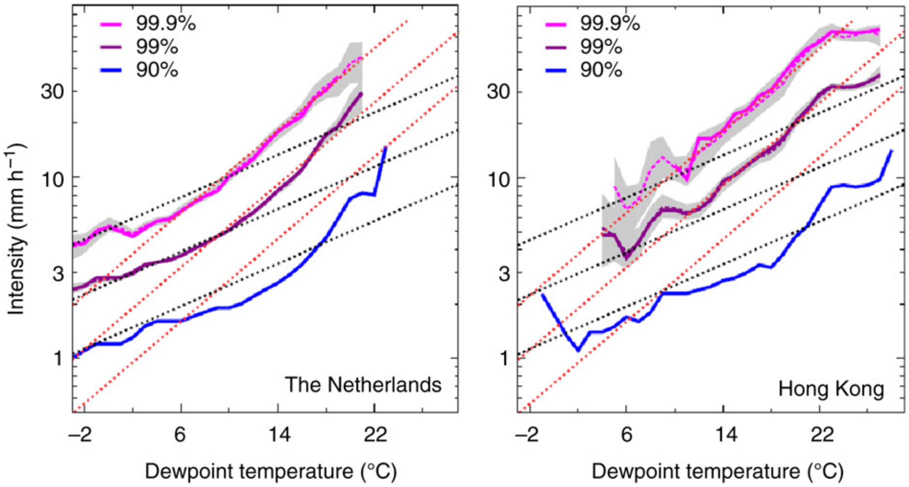

Figure 3 Scaling of hourly precipitation intensity with surface dew-point temperature in the Netherlands and Hong Kong, derived from observations (Lenderink, G., H. Y. Mok, T. C. Lee, and G. J. van Oldenborgh, 2011: Scaling and trends of hourly precipitation extremes in two different climate zones – Hong Kong and the Netherlands. *Hydrol. Earth Syst. Sci. Discuss.*, **8**, 4701–4719, http://dx.doi.org/10.5194/hessd-8-4701-2011). The black dotted line shows the Clausius–Clapeyron scaling of approximately 7% per degree Centigrade, whereas the purple dotted line shows twice this rate increase (14% per degree Centigrade).

information on one hand, and bottom–up information needs at the level of impact assessment and vulnerability analysis on the other. Applied this way, the scenarios help in defining the adaptation tipping points, where the driver for action is not any changes in climate statistics but the inability to meet sustainability and protection criteria. For these, changing climate statistics is only one of the issues, next to socioeconomic developments (Kwadijk et al. 2010). The case studies explored earlier are described as a series of examples of how climate change scenarios can help in making society relevant vulnerability assessments and developing adequate adaptation options. Rather than relying on a single or consensus-based climate model projection, a range of scenarios is constructed with a strong link to the major large-scale drivers of weather phenomena in the Dutch area. They should not be considered as a representation of all possible future climate conditions, but reflect a number of relevant pictures. The standard output variables are inspired by the wide range of sectors that make use of them, with a focus on extremes that have the potential to disrupt society (such as changes in multiday precipitation extremes for the Rhine area). They allow a contextual assessment, by focusing on areas where many people live (in the coastal zone and along the Rhine and Meuse river banks). Although they focus on the climate time scale of half a century and longer, many studies have used them for shorter projection horizons. The new generation of climate change scenarios, KNMInext, will increasingly address this 10–30 year time scale, including a much stronger emphasis on natural weather variability and current trends.

The structure and range of KNMI'06 allows rapid assessments for a wide range of relevant climate conditions, including those to which a specific sector or area is particularly vulnerable. Moreover, the scenarios provide the indispensable structure for an integrated approach that allows comprehensive analysis of the uncertain future climate, and makes optimal use of climate knowledge embedded in theory, models, and observations.

Information transfer between climate science and socioeconomic impact assessment is subject to an optimal update time scale. The time scale of scientific progress is not necessarily compatible with the time scale of policy implications of any changes in climate statistics. Climate change assessments for various sectors in the Dutch Delta often require extensive model simulations and stakeholder involvement. This 'assessment chain' has an inherent inertia that cannot be ignored. This inertia is related not only to the decision-making process chains embedded in operational policy and management practices but also to the fact that climate scenarios should reflect robust scientific findings. Therefore, even highly relevant and well-understood new insights in the scientific arena need to go through a 'time filter' process to avoid unmanageable information inputs in the chain. Guidance of existing climate information therefore is often a more powerful tool to have this information percolate into the management chain than rapid updates of guiding scenarios.

The other side of the chain, the vulnerability assessment, can be typed likewise. Unexpected climate-related impacts (such as an inland dike breach or salt water intrusion due to excessive drought in 2003), (re)assessment of policy implications (such as the influence of flood protection measures in Germany on the design discharge in the Netherlands), or changing economic factors (such as the discount rates relevant for planning long-term investments) all frequently put climate vulnerability in an altered perspective.

An intensive collaboration of Dutch climate scientists and experts in local impact assessment, delta technology, spatial planning, and socioeconomic translation has developed significantly during the past decade. Large infrastructure projects like the Delta Programme and well-designed research and stakeholder participation programs such as Climate Changes Spatial Planning and Knowledge for Climate have helped creating these networks. Future developments will continue to challenge the understanding of the many interactions between climate and human dimensions at multiple scales, and will continue to call for this kind of research networks.

5.18.1 Coastal Ecosystems: Geomorphic Elements, Species, and Cities

A coastal ecosystem includes estuaries, coastal waters, and lands located at the lower end of drainage basins, where stream and river systems meet the sea and are mixed by tides. The coastal ecosystem includes saline, brackish (mixed saline and fresh), and fresh waters, as well as coastlines and the adjacent lands. All these water and landforms interact as integrated ecological units. Shorelands, dunes, offshore islands, barrier islands, headlands, lagoons, and freshwater wetlands within estuarine drainages are included in the definition of coastal ecosystem since these interrelated features are crucial to coastal wildlife and their habitats. A variety of animals and plants complete the ecological system. The definition of coastal ecosystem may also potentially apply to lacustrine areas, where bodies of freshwater play an ecological role similar to oceans. For instance, bird populations of the same species are found both in lacustrine and coastal ecosystems. This is the case of the Snowy Plover, for example, that is found along the shores of inland lakes in the United States and along the west coast of Florida and California (Convertino et al. 2011a). The aforementioned definition of coastal ecosystem considers only the environmental features of coastal ecosystems. However, 'anthromes' are part of coastal ecosystems. Anthromes represent the global ecological patterns created by sustained direct human interactions with ecosystems. Thus, anthromes are focused on the human components of ecosystems rather than on their natural components. Therefore, a comprehensive definition and analysis of coastal ecosystems, including biomes and anthromes together, seems fundamentally important for better projections of climatic change effects and management scenarios. This involves the use of integrated modeling frameworks and translates into better decision-making evaluation of alternatives to face climatic change (Kiker et al. 2005; ECA 2011; Karvetski et al. 2011).

In the following, we focus our attention on the relationships between hydrological, ecological, and climatological variables of two coastal ecosystems in which the biotic and the anthropic components exert a prevalent role, respectively: Florida (Gulf of Mexico coast) for the former case and Venice (Italy) for the latter case. Figure 1 shows the two case studies under flooding events: St. Marco Square in Venice and Santa Rosa Island in Florida. In both cases, flooding phenomena, which are mostly triggered by different climatological stressors, produce relevant economic losses to the coastal ecosystem. For the Gulf Coast of Florida, we focused our attention on the effect of floods on long-term wetland evolution and risk assessment of shorebirds, while for Venice we investigated the effects of the pressure–wind combination on tidal levels in the city. Florida and Venice can be thought of as a complex of human and natural systems at different scales strongly affected by sea level rise (SLR). Here, the focus is on the natural component of the Florida ecosystem and on the human component of the Venice ecosystem. Nonetheless, SLR also affects species in the Venice lagoon (Marani et al. 2004, 2007, 2010) and urbanized cities along the coast of Florida (Elsner et al. 2008; Weiss et al. 2011).

5.18.2 Materials and Methods

5.18.2.1 Global Sea Level Rise, Local Sea Level Rise, and Storm-Related Stressors

Global SLR due to climatic change would affect many sensitive coastal areas around the world.

An increasing long-term linear trend of SLR has been observed; however, in recent years sea level has actually reduced the speed of its increase. Thus, SLR is clearly not accelerating, but it appears to increase (Rohling et al. 2008; Church and White 2011). It is estimated that almost 50% of the worldwide population live along or nearby coastal areas within 100 km from the coastline (WRI 2000; SEDAC 2011). Thus, there is the urgent need to understand how climate affects coastal areas and how to design protection interventions to limit damages to human and natural components of coastal ecosystems.

We define in the following some hydrological phenomena potentially affected by SLR. These processes are useful in the analysis of the Florida and Venice case studies. Although there are similarities, these processes tend to be treated separately because of their partial independency.

Local mean sea level (LMSL) is defined as the height of the sea with respect to a land benchmark, averaged over a period of time (such as a month or a year typically) long enough that fluctuations caused by waves and tides are smoothed out. Eustatic change (as opposed to local change) results in an alteration to the global sea levels, such as changes in the volume of water in the world oceans or changes in the volume of an ocean basin. We will refer to the latter as global SLR.

Overwash is the flow of water and sediment over the crest of the beach that does not directly return to the water body (such as ocean, sea, bay, or lake; hereafter, ocean) where it originated after water level fluctuations return to normal. There are two kinds of overwashes: overwash by runup and overwash by inundation.

Tides are the rise and fall of sea levels caused by the combined effects of the gravitational forces exerted by the Moon the Sun, and the rotation of the Earth. While tides are usually the largest source of short-term sea level fluctuations, sea levels are also subject to forces such as wind and barometric pressure changes, resulting in storm surges, especially in shallow seas and near coasts.

A storm surge is an offshore rise of water associated with a low-pressure weather system, typically tropical cyclones and strong extratropical cyclones. Storm surges are caused primarily by high winds pushing on the ocean's surface. The wind causes the water to pile up higher than the ordinary sea level. Low pressure at the center of a weather system also has a small secondary effect, as can the bathymetry of the body of water. It is this combined effect of low pressure and persistent wind over a shallow water body that is the most common cause of storm surge flooding problems. The term 'storm surge' in casual (nonscientific) use is storm tide; that is, it refers to the rise of water associated with the storm, plus tide, wave run-up, and freshwater flooding.

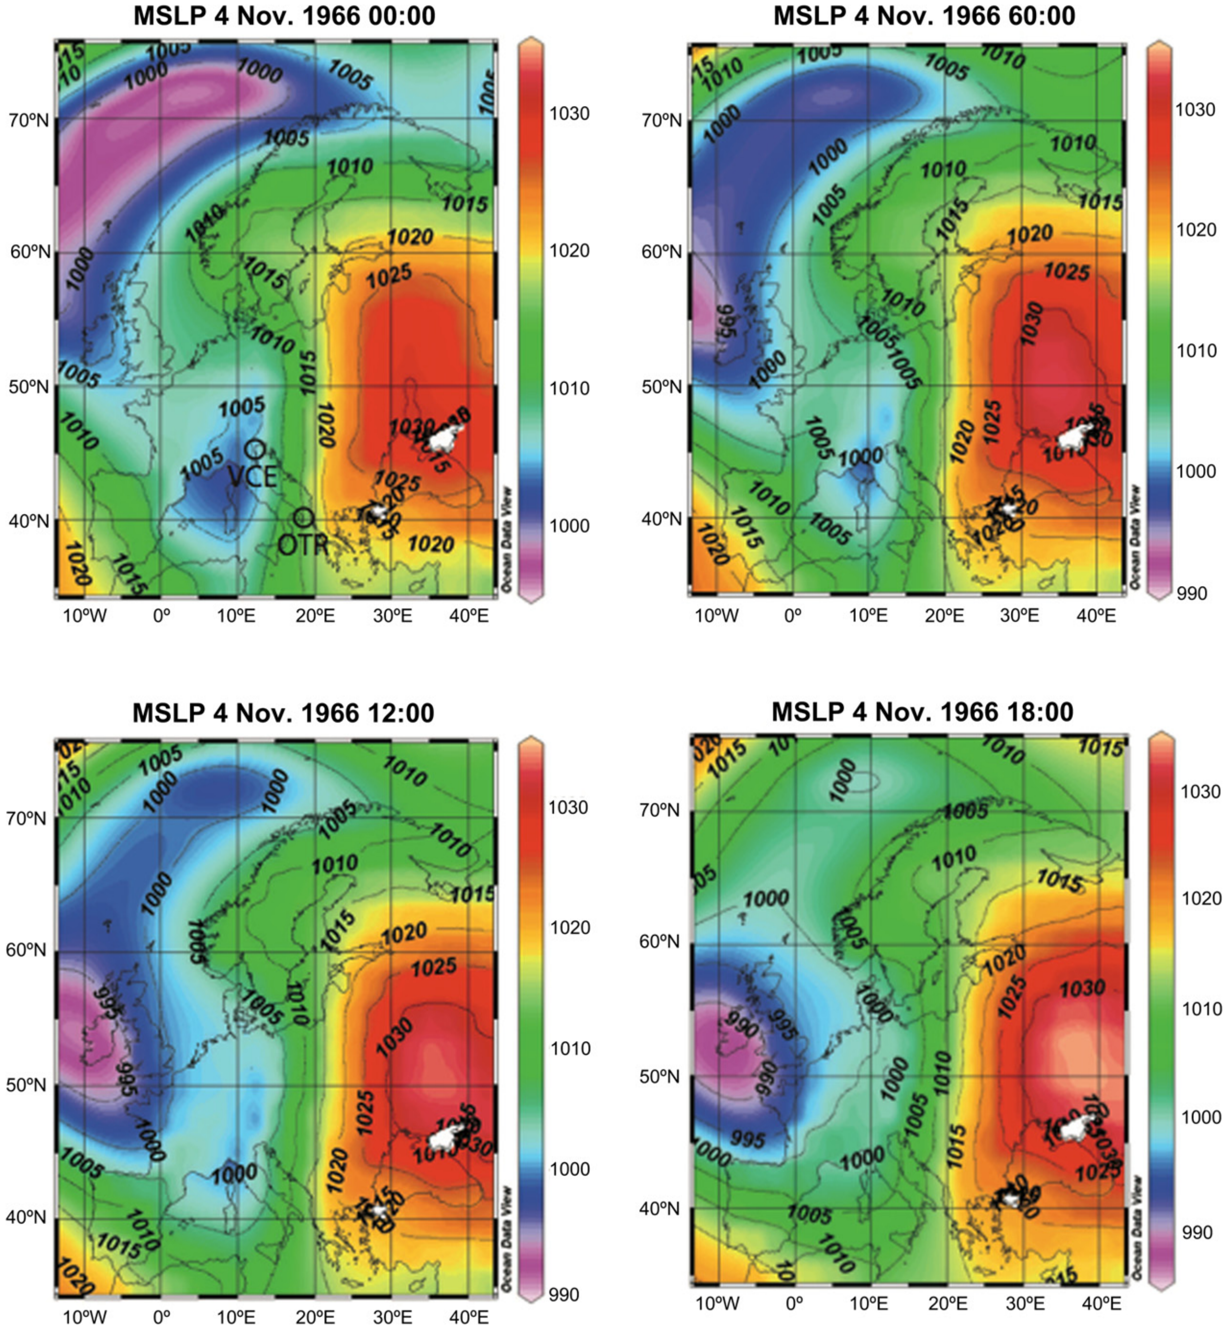
A hydroperiod can be defined as the number of days per year that an area of land is wet or the length of time that there is standing water at a location.

5.18.2.2 Florida and Venice: Similarities and Contrasting Elements

In Venice, exceptional tides (when the waterline is equal to or more than 140 cm on the mareographic zero of 'Punta della Salute,' located near the Salute Church, in front of St. Mark's Square (Carbognin et al. 2010)) statistically occur once every 4 years. Exceptional tides are caused by a combination of various factors, such as the astronomical tide, low pressure on the Tyrrhenian Sea, strong south wind ('Scirocco'), and the Adriatic seiche. Further, two larger phenomena also contribute to the increase in the water level: eustasy and the subsidence of the Venetian Lagoon, which, together, have caused an altimetric loss of about 26 cm in the past century (Gambolati et al. 1974; Rinaldo et al. 2008; Carbognin et al. 2010). High water depends on the tide cycle (the alternation of high and low tides happens every 6 h): when there is 'acqua alta' (high water) on the streets, it lasts only a few hours during the peak of the high tide (usually 3–4 h). Once water goes down, things go back to normality. On average, Venice is characterized by a semidiurnal tide (tidal period $T = 12.4$ h) and lagoon microtidal (tidal amplitude $a = 0.5$ m) extending over an area of roughly 550 km^2 (Rinaldo et al. 2008; Toffolon and Lanzoni 2010). Four big flooding events are in the memory of Venice inhabitants (Rinaldo 2009): the 194-cm high water (meteorological tidal level) event in November 1966 at 12:00 p.m., the 158-cm event in February 1986 at 00:00 a.m., the 142-cm event on 8 December 1992 at 00:00 a.m., and the 144-cm event in November 2000 at 6:00 p.m. In 1966, an unusual combination of high tides and a relentless sirocco wind sent floodwaters surging through the city's canals and spilling over into its historic palaces and piazzas. Priceless art works were ruined, and thousands of people were trapped in their homes (Rinaldo 2009). Another 5000 were left homeless. The 'great flood' in 1966 sparked an intense debate on how to save the World Heritage city from the ravages of flooding (Gambolati et al. 1974; Harleman et al. 2000; Bras et al. 2001; Pirazzoli and Umgiesser 2003; Comerlati et al. 2004; Castelletto et al. 2008; Rinaldo 2009). The final solution was the design and construction of the 'Mo.S.E' ('Modulo Sperimentale Elettromeccanico'; in English, 'Experimental Electromechanical Module') consisting of rows of mobile gates able to isolate the Venetian Lagoon from the Adriatic Sea when the tide reaches above an established level (110 cm) and up to a maximum of 3 m. The Mo.S.E. is going to be in fully operative in 2012 (Carbognin et al. 2010). We considered the 1966, 1986, 1992, and 2000 events in our analysis. Two other events, which happened on 1 December 2008 and 25 December 2009, registered a tidal level of 156 cm and 145 cm, respectively. However, the latter events were not considered for the lack of wind data. Figures 2 and 3 show the global circulation patterns of pressure and wind velocity for the 1966 high-water event.

The tidal cycle in Florida has been much less studied than in Venice. However, the tidal excursion in the Gulf of Mexico is quite moderate with respect to that in Venice. In the Gulf of Mexico for the semidiurnal tides, the times of maximum tidal current generally lead the high tide at St. Petersburg (Florida) by 2–9 h. On the other hand, the maximum tidal currents of the diurnal tide lag the high tide time at St. Petersburg by 10–20 h (He and Weisberg 2002). The east coast of Florida (Atlantic Ocean) exhibits semidiurnal tides, whereas most of the west coast of Florida exhibits mixed tides and most of the Panhandle of Florida Gulf Coast has diurnal tides. While in Venice the persistence of the pressure gradient over the Adriatic Sea is mainly responsible for the enhanced tides, in Florida tropical cyclones are responsible for the overwash phenomena. A tropical cyclone is a storm system characterized by a large low pressure center and numerous thunderstorms that produce strong winds and heavy rain. Florida is consistently affected by tropical cyclones of different categories (from tropical depression to hurricanes) in the summer season. The 2004 Atlantic hurricane season officially began on 1 June 2004 and lasted until 30 November 2004. These dates conventionally delimit the period of each year when most tropical cyclones form in the Atlantic basin. The season was notable as one of the deadliest and costliest Atlantic hurricane seasons on record in the past decade, with at least 3132 deaths and roughly 50 billion (2004 USD; 58.1 billion 2011 USD) in damage. The most notable storms for the season were the five named storms that made landfall in the US state of Florida, three of them with at least 115 mph (185 km h^{-1}) sustained winds: Hurricanes Charley, Frances, Ivan, and Jeanne, and Tropical Storm Bonnie. This is the only time in recorded history that four hurricanes affected Florida.

Thus, pressure gradients and wind velocity with different magnitudes affect Florida and Venice, causing enhanced flooding phenomena. Florida is typically characterized by low-frequency, very intense vertical pressure gradients that form in



MSLP 4 Nov. 1966 00:00

MSLP 4 Nov. 1966 60:00

MSLP 4 Nov. 1966 12:00

MSLP 4 Nov. 1966 18:00

the ocean and moves inland with high speed in the summer season. On the contrary, Venice is characterized by medium low-frequency pressure gradients over a large area and moderate wind speed in the winter season.

5.18.3 Results and Discussion

5.18.3.1 Venice: Tide and Storm Surge

The climatological and hydrological drivers of the 'high water' phenomena in Venice have been analyzed. The first objective was to perform a comparative analysis of the ERA-40 reanalysis (ERA40 2011), simulation data, observations of wind velocity, mean sea level pressure (MSLP), and tidal levels and to detect the key variables for 'high water' forecasting. The effort was in analyzing global patterns from maps and time series of meteorological variables. We found that, for the MSLP, the observed and ERA-40 values are in agreement, while for the wind velocity, ERA-40 overestimates or underestimates the observed values. We also found evidence of correlations between the MSLP gradient, wind velocity, and meteorological tidal level.

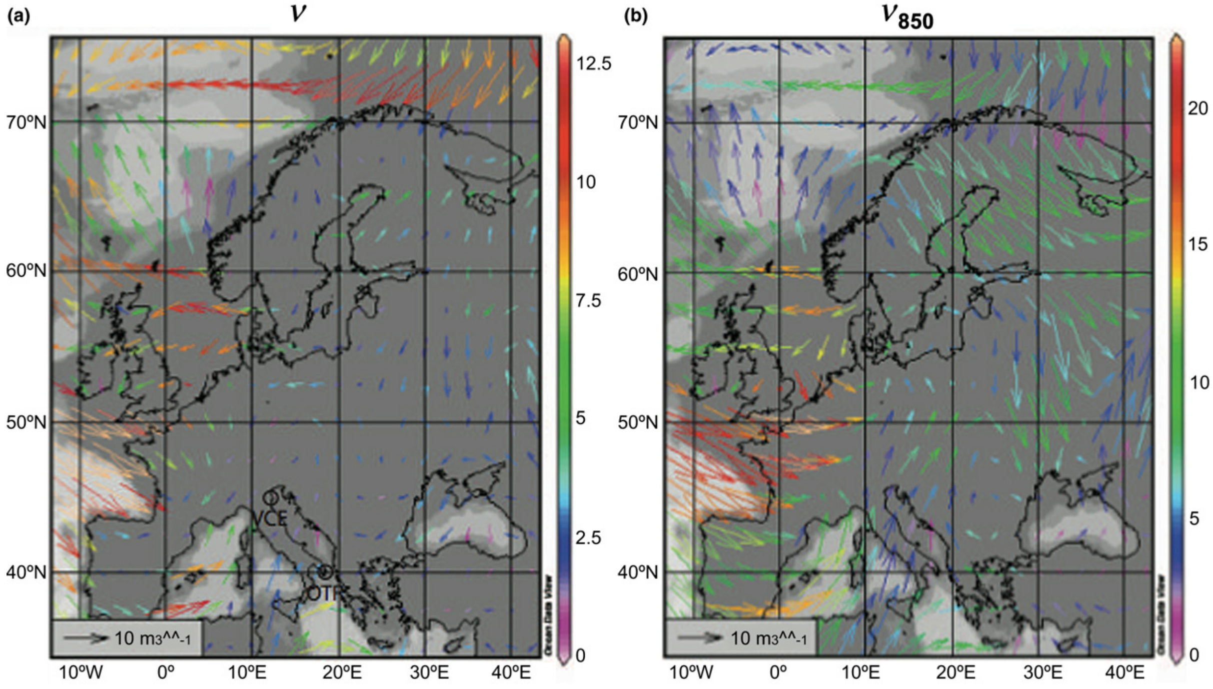

Figure 3 Wind velocity for 4 November 1966. Global circulation patterns (a) for the wind velocity at surface and (b) at 850 hPa (v and $v850$) (m s^{-1}) over Europe (at 12:00).

A concurrence of MSLP gradient, wind velocity, and high water peaks was observed. The second objective was to detect changes in the signatures of flooding phenomena in Venice and to relate them to global atmospheric circulation patterns (Figures 2 and 3). Previous analysis of the tidal regime in Venice during the past century showed that the frequency and magnitude of high tides are correlated to interdecadal climatic oscillations (Fagherazzi et al. 2005; Rinaldo et al. 2008; Rossa et al. 2010).

Figure 4 shows the wind speed at 850 hPa and at surface (m s^{-1}), the MSLP p (Pa), and the tidal level TL (cm) for Venice (green dots) and Otranto (red dots) on 4 November 1966. There is a strong correlation among wind velocities, pressures, and tidal level in Venice. The pressure–velocity–tidal level pattern is remarkably observed also for the 1986, 1992, and 2000 events. The wind velocities at the surface in Venice and Otranto are quite similar; however, the wind velocity at 850 hPa is predominantly higher in Otranto than in Venice. This contributes to the storm surge in Venice and is also a by-product of the pressure gradient Otranto–Venice. There was a peak in the velocity and pressure and, consequently, after a negligible delay, a peak in the tidal level.

Figure 5 reports the ERA-40 reanalysis and the observed pressure gradient over the Adriatic Sea (Otranto–Venice) of the 4 November 1966 event. The ERA-40 reanalysis is capable of representing on average the observed pressure gradient. However, the ERA-40 reanalysis velocity (both at surface and at 850 hPa) underestimated the observed velocity (Figure 4). The temporal recurrence of the wind velocity vs. the Otranto–Venice pressure gradient is shown in Figure 6 for the 1966, 1986, 1992, and 2000 events. $v \sim 1.9\Delta p$ and $v850 \sim 0.8\Delta p$ are the linear relationships assessed for the velocity and surface and at 850 hPa with coefficient of determination R^2 equal to 0.46 and 0.68, respectively.

Figure 7 shows the negative correlation between the tidal level and MSLP in Venice for the month of November from 1924 to 2001. For a low MSLP, a high value of tidal level is observed and vice versa. The correlation coefficient is 0.61. For a low MSLP in Venice, a high MSLP is observed in Otranto. The difference in pressure between the two cities creates the pressure gradient responsible for the storm surge in Venice. Figure 8 shows a comparison between modeled (ERA-40 reanalysis) and observed wind velocity at surface and MSLP for Venice in 1966, 1986, 1992, and 2000. The plots show that ERA-40 underestimates and overestimates the observed velocity without a particular trend. This was already evidenced in Figures 4 and 5. As for the MSLP – in this case in Venice – ERA-40 reproduces the observed MSLP extremely well. R^2 is 0.52 and 0.93 for the regressions in Figure 8, top and bottom plots, respectively.

Regardless of the persistency of the pressure gradient Otranto–Venice – demonstrated for all the ‘acqua alta’ events considered – recent studies found that the frequency of extreme storm surge events affecting Venice is projected to decrease by about 30% by the end of the twenty-first century (Troccoli et al. 2011). In addition, a trend assessment based on tidal observations by Troccoli et al. (2011) found a reduction in extreme tidal levels. Extrapolating the current +17 cm per century sea level trend, these results suggested that the frequency of extreme tides in Venice might largely remain unaltered under the projected twenty-first century climate simulations.

5.18.3.2 Florida: Habitat Overwash, Tropical Cyclones, and Species Risk Assessment

Florida coastline-dependent species are characterized by a very high potential of extirpation risk because of SLR

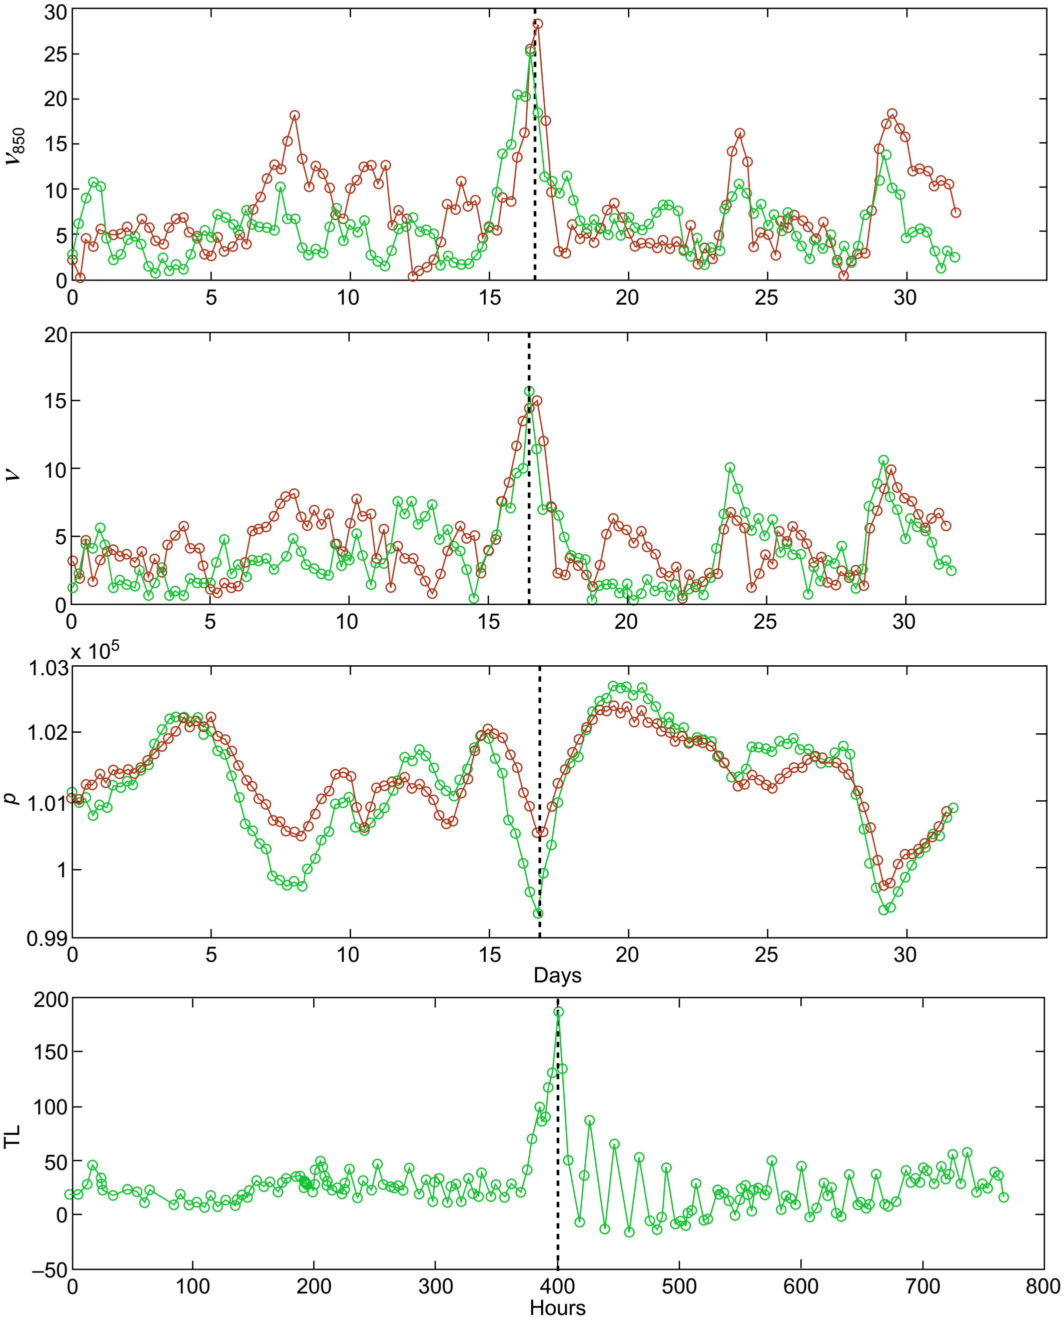

Figure 4 Correlation among global climatological variables and local hydrological variables. Wind speed at 850 hPa and at surface (m s^{-1}), mean sea level pressure p (Pa), and tidal level TL (cm) for Venice (green dots) and Otranto (red dots) on 4 November 1966.

(Aiello-Lammens et al. 2011) and a possible future increase in tropical cyclone activity (Convertino et al. 2011b) The Snowy Plover (*Charadrius alexandrinus nivosus*, SP) (**Figure 9**) is a threatened species resident in Florida and was considered as a sentinel species to understand the effect of climate on the Florida coastal ecosystem (Convertino et al. 2011c). The geographic range of the Snowy Plover is along the Gulf of Mexico coast of Florida; thus, we considered only this region in the modeling effort. Through the Strategic Environmental Research and Development Program (SERDP) SI-1699 (Linkov 2009; Convertino et al. 2011c) led by the US Army Engineer Research and Development Center and the University of Florida we integrated a land-cover model (Sea Level Affecting Marshes Model (SLAMM)) (Clough 2010), a habitat suitability model (MaxEnt) (Phillips and Miroslav 2008), and an ecological metapopulation model (RAMAS) (Akcakaya 2005). We predicted the geomorphological changes of the Gulf of Mexico coastal habitat in Florida, assessed the habitat suitability of the Snowy Plover, and calculated the Snowy Plover extirpation risk at relevant time and spatial scales in 2100

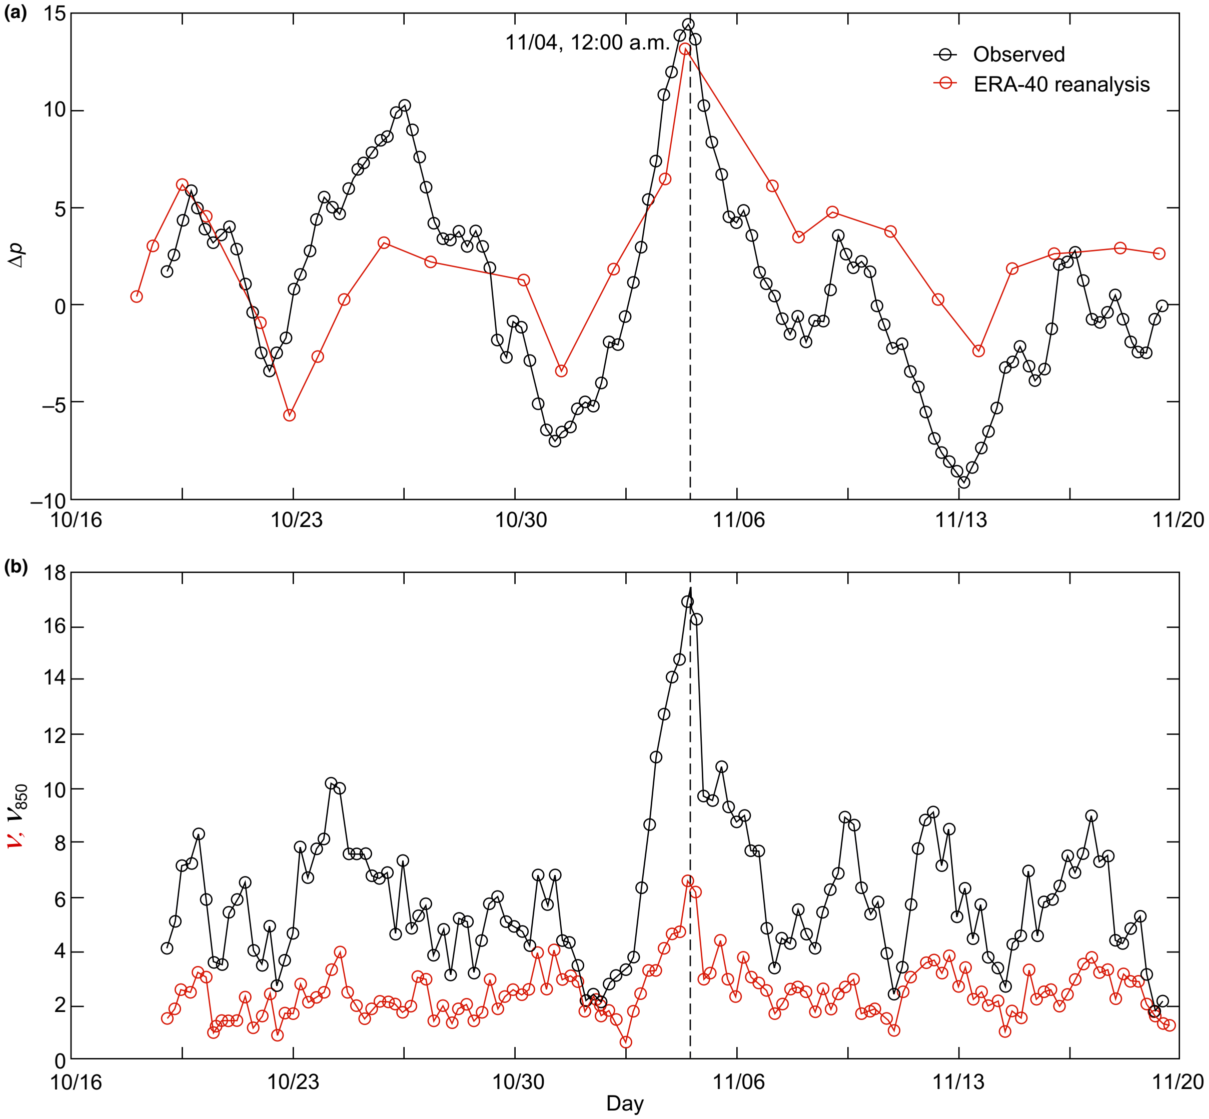

Figure 5 Intermonthly pressure gradient and wind velocity for the 4 November 1966 event. (a) ERA-40 reanalysis and observed pressure gradient over the Adriatic sea (Otranto–Venice). (b) ERA-40 reanalysis wind velocity at surface and at 850 hPa for Venice.

(Convertino et al. 2011d; Chu-Agor et al. 2011a; Aiello-Lammens et al. 2011). Particular attention was given to testing the uncertainty of the projections related to the model input factors (see Section 5.18.3.4) and to verify a priori assumptions and modeling results among climatological, geomorphological, and ecological variables.

In particular, Convertino et al. (2011a,b) investigated the relationship between the probabilities of the presence of a nesting ground of the Snowy Plover and tropical cyclone occurrence and between the probability of the absence of a nesting ground and renourishment interventions occurrence. A Bayesian inference was utilized considering the historical occurrences of the Snowy Plover nests, the historical Atlantic cyclones, and the renourishment interventions (Figure 9). The odds ratio was defined as the ratio of the odds of a nesting ground in the spring following a year with at least one tropical cyclone to the odds of a nesting ground in the spring following a year without a tropical cyclone. The frequencies were based on 104 Monte Carlo samples. The median odds ratio – considering nesting grounds and cyclones – is 7, and the mean is 11. The maximum likelihood estimate is a lognormal distribution (red curve), and the coefficient of determination is $R^2 = 0.87$ (Figure 10(a)). Figure 10(b) shows the posterior probabilities of absence of the odds ratio – considering nesting grounds and renourishments – in the breeding season. The odds ratio is in this case the ratio of the odds of a nesting ground in the spring following a year with at least one renourishment event to the odds of a nesting ground in the spring following a year without a renourishment intervention. For the breeding season, the median odds ratio is 2.5 and the mean is 4.9. The maximum likelihood estimate is a lognormal distribution, and the coefficient of determination is $R^2 = 0.92$.

The higher percentage of flat areas on the beach, created by cyclones, that translates to an increased open view of the

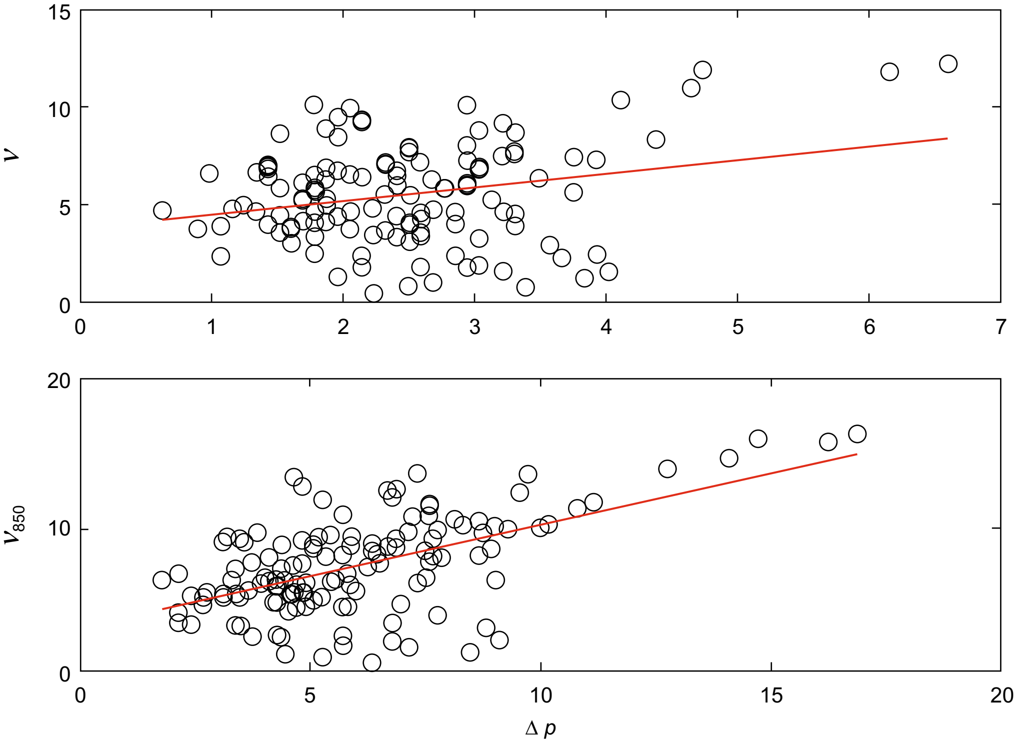

Figure 6 Wind velocity vs. observed pressure gradient for the 1966, 1986, 1992, and 2000 events. Wind speed at surface and at 850 hPa in Venice vs. the pressure gradient Otranto–Venice. The coefficient of determination R^2 is 0.46 and 0.68 for the former and the latter regression, respectively.

habitat (Gornish and Miller 2010), the presence of diffuse debris, and the large amount of organic material on the beach increase the favorability of the shores to be a breeding ground for the Snowy Plover (Convertino et al. 2011d). As for the renourishments, we argued that the decrease in the documented nest abundance of the Snowy Plover resulted from an altered cross-sectional beach profile, which is not favorable for nesting and foraging. As a consequence, nesting success is reduced because of habitat modifications and possible direct disturbance of renourishment interventions.

The quantified positive and negative feedbacks between the Snowy Plover, tropical cyclones, and renourishments are very useful in metapopulation modeling. In fact, metapopulation models (e.g., RAMAS) also reproduce stochastic events like cyclones and their effect on the modeled species. We disregarded the hypothesis of the catastrophic effect of cyclones on the Snowy Plover; thus, we avoided underestimating the abundance of nesting grounds of the species in time.

5.18.3.3 Wetland Evolution and Two-Dimensional Flood Modeling

Flooding risk maps are a key component of risk management of coastal areas (Grimaldi et al. 2009). Effective shoreline management planning requires broad-scale and long-term coastal flood risk analysis (Harvard Business School 2007).

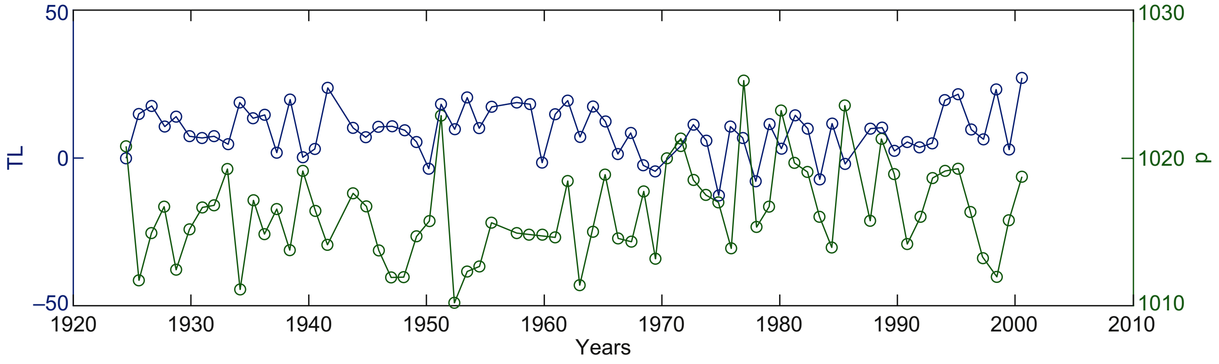

Figure 7 Tidal level vs. monthly averaged MSLP for November from 1924 to 2001. The tidal level (cm) and the monthly averaged MSLP for Venice are compared through the years.

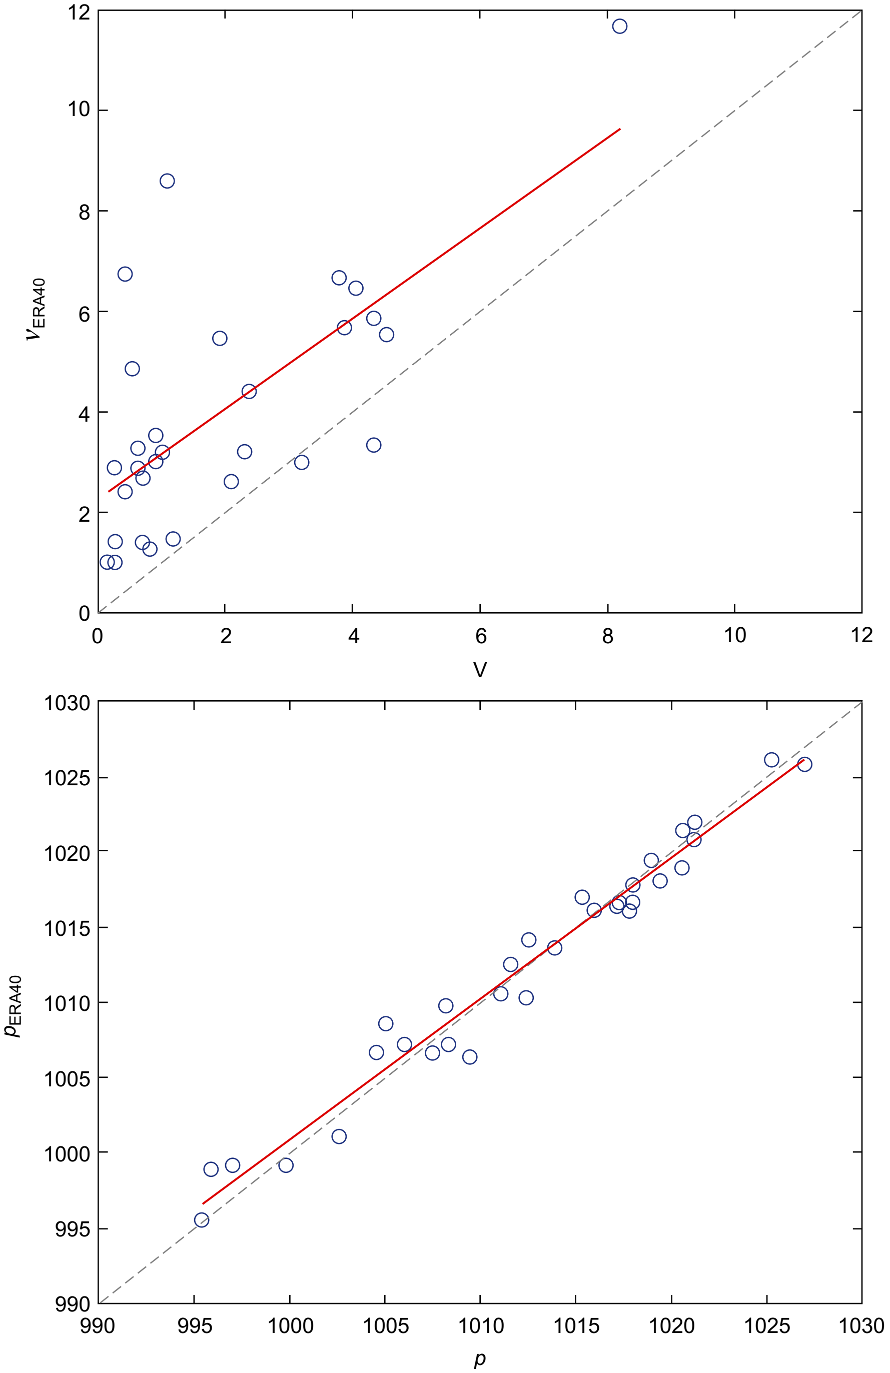

Figure 8 ERA-40 reanalysis vs. observed wind velocity and mean sea level pressure. The graphs show a comparison between modeled and observed wind velocity at surface and MSLP for Venice in 1966, 1986, 1992, and 2000.

Such work has become more necessary, and challenging, as SLR and changes in other climatic variables have become more evident. Coastal boundary conditions tend to complicate flood risk analysis. In particular, the close coupling between flooding and shore morphology introduces considerable uncertainty, because beach level is a major determinant in the reliability of flood protection structures and suitability of the habitat for species.

For operational purposes, most flood inundation modeling is carried out using one-dimensional (1D) and pseudo-2D methods (1D for river segments and 2D for open areas such as estuaries/delta, ocean, and floodplains). As for our Florida study, the habitat considered for modeling was derived by an inundation scenario that does consider the heterogeneities in the elevation of lands when inundated but not the presence of infrastructure. For safety purpose, a hypothetical 10-km

Figure 9 Snowy Plover nests, cyclones, and renourishments in Florida. Nesting dataset of Snowy Plovers from 2002 to 2010 (dots) and tracks of the tropical cyclones (tropical depression (TD), tropical storm (TS), hurricane (H)) in the period 2001–09 from NOAA (2010) of the North Atlantic tropical cyclone database. The renourishment projects in Florida have been represented (Convertino et al. 2011b). A Snowy Plover is in the picture in the lower left corner. (1) is the Northwest Florida region (Santa Rosa Island (SRI) is included), (2) is the Apalachee Bay region, and (3) is the Southwest Florida region. [Available online at htttp://www.plosone.org/article/info:doi/10.1371/journal.pone.0015683.]

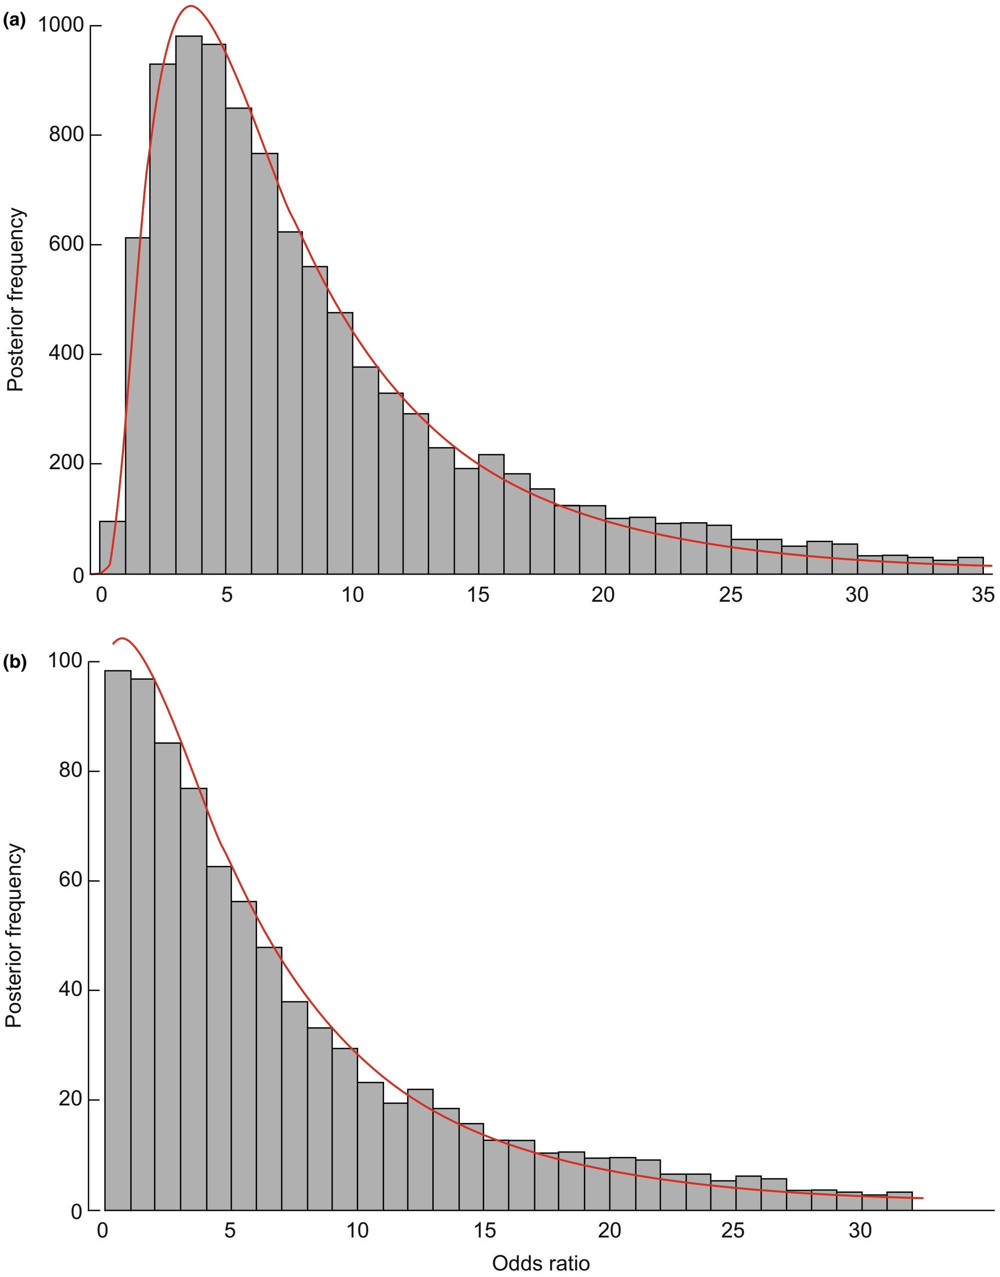

Figure 10 Bayesian estimation of probability of occurrence of a Snowy Plover nest. (a) Posterior frequencies (of presence) of the odds ratio between the odds of a breeding ground in the spring following a year with at least one tropical cyclone to the odds of a breeding ground in the spring following a year without a tropical cyclone (Convertino et al. 2011b). [Available online at http://www.plosone.org/article/info:doi/10.1371/journal.pone.00156]. (b) Posterior frequencies (of absence) of the odds ratio in the breeding season between the odds of a breeding ground in the spring following a year with at least one renourishment event to the odds of a breeding ground in the spring following a year without a renourishment intervention (Convertino et al. 2011a). Reproduced from Convertino M., J. F. Donoghue, M. L. Chu-Agor, G. A. Kiker, R. Munõz-Carpena, R. A. Fischer, and I. Linkov, 2011a: Anthropogenic renourishment feedback on shorebirds: a multi- species Bayesian perspective. *J. Ecol. Eng.*, 37, 1184–1194.

inundation distance from the coast was considered as inundation scenario in 2100 (Convertino et al. 2011d). The habitat within this distance was modeled using the land-cover model SLAMM. SLAMM considers a fixed inundation depth, for each SLR value for each year over the domain. This assumption is notoriously physically unrealistic; thus, an elevation-dependent inundation depth would be desirable to predict realistic inundation scenarios. Figure 11 shows a typical SLAMM land-cover output for the Santa Rosa Island along the north Gulf of Mexico coast of Florida (Figure 9). Figure 12(c) shows the changes in the area of the beach habitat that consists of estuarine beach, tidal flat, and ocean beach (constituted of alkaline medium/fine white sand and silt) for the Santa Rosa Island at different SLR scenarios ((0.2; 2.0) m) (Chu-Agor et al. 2011a).

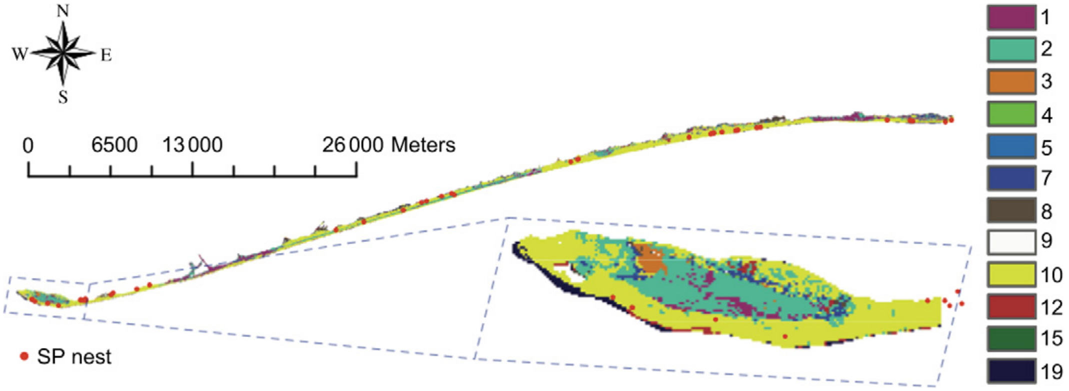

Figure 11 Ecosystem composition for the Santa Rosa Island in 2006. The land-cover classes for the Santa Rosa Island (SRI) are developed dryland (1), undeveloped dryland (2), swamp (3), cypress swamp (4), inland fresh marsh (5), scrub/shrub-transitional marsh (7), salt marsh (8), mangrove (9), estuarine beach (10), ocean beach (12), inland open water (15), and open ocean (19). The red dots are the 2006 nest occurrences of the Snowy Plover that has been taken as the 'sentinel species' of SLR in the SERDP Project 1699.

The beach habitat (composed of estuarine beach, tidal flat, and ocean beach), which occupies 1.4% (2683 ha) of the Eglin Air Force Base (AFB), is one of the most important habitat class for the Snowy Plover population. Eglin AFB hosts about 20% of the overall Snowy Plover population in Florida. As expected, the beach habitat posted an increase in area gained from the losses in higher elevation habitats (most probably marshes) (Chu-Agor et al. 2011a). For the first 30 years (2010–40), the beach is expected to increase by a maximum amount of 3% (81 ha). However, from 2050 forward, the area will decrease gradually until the end of the century, posting a net gain of 2.0% (54 ha). It is surprising to note that the different SLR projections have the same effects on beach habitat (Figure 12) despite the fact that the beach interfaces with the ocean (Chu-Agor et al. 2011a). For modeling the whole Gulf Coast of Florida, the SLR curve of the Intergovernmental Panel on Climate Change (IPCC) A1B (IPCC 2001) scenario was rescaled, fixing a 2-m SLR in 2100 (Figure 12(a)). Values of SLR are constant over the modeled domain extended 10 km from the coast.

Two-dimensional flood modeling differs from 1D flood modeling in that it simulates differing flow conditions across a potential floodplain, represented as a 2D grid of cells (Nardi et al. 2008). A 2D hydrodynamic model divides the floodplain into a gridded domain (down-stream and cross-stream directions) in which complex obstacles, such as buildings, can be taken into account. Linear landscape elements are stored by combining raster (elevation) and vector (linear elements) data. Elements that may affect flood patterns are selected from a vector database. Further, 2D simulations represent an effective tool for floodplain and coastal managers to improve the prediction and management of flood hazards for those areas where the loss of channel conveyance and SLR result in large unconfined overland flow with extensive floodwave attenuation (Allsop et al. 2009). These tools can indubitably provide better predictions of flooded areas that are the inputs of geomorphological or land-cover models, which subsequently provide the inputs for metapopulation models. Thus, the combination of 2D models, which provide a spatially variable depth over the modeled domain, with geomorphological and/or land-cover models, would dramatically increase the accuracy of scenarios of landscapes and species distributions.

5.18.3.4 Models' Global Sensitivity and Uncertainty Analysis

Untangling the drivers and sources of uncertainty in mathematical models is fundamentally important to provide a reliable basis for predictions, for example, of species habitat, in the future under climatic changes. We performed a global sensitivity and uncertainty analysis (GSUA) (Saltelli et al. 2004; Campolongo et al. 2007; Munoz-Carpena et al. 2010; Chu-Agor et al. 2011a,b; Convertino et al. 2011) for the models involved in the case study of Florida (SLAMM, MaxEnt, and RAMAS) for the Snowy Plover (*C. alexandrinus nivosus*), a species highly threatened by SLR. The importance of and contribution to the uncertainty of the output has been evaluated for the intrinsic input factors of the models and the exogenous site-specific input factors. In general, the uncertainty analysis propagates the uncertainties in the model's inputs to its outputs, while sensitivity analysis determines the contribution of each input factor to the uncertainty of the outputs. Uncertainty and sensitivity were evaluated using a two-step GSUA method: the screening method proposed by Morris (1991) and a variance-based technique proposed by Sobol (1993). The Morris method provides a qualitative assessment of the importance of each input factor, while the Sobol method performs a quantitative analysis of sensitivity and uncertainty.

For the land-cover model (SLAMM), GSUA results showed that the variability in the change in area of the higher elevation wetlands (swamps and inland fresh marsh) was attributed in general to the DEM vertical error for the lower elevation range zone (0–1 m) (95–99%) and to the historic trend of SLR (1–2%) (Chu-Agor et al. 2011a). Interactions between the input factors for these wetlands were negligible. Higher-elevation wetlands showed a general decrease in area from 2060 to 2100 and from minimum to maximum SLR scenarios. This further confirmed that the most important processes involved in the fate of the coastal habitat in Eglin AFB were inundation (reduction in elevation due to SLR) and accretion/

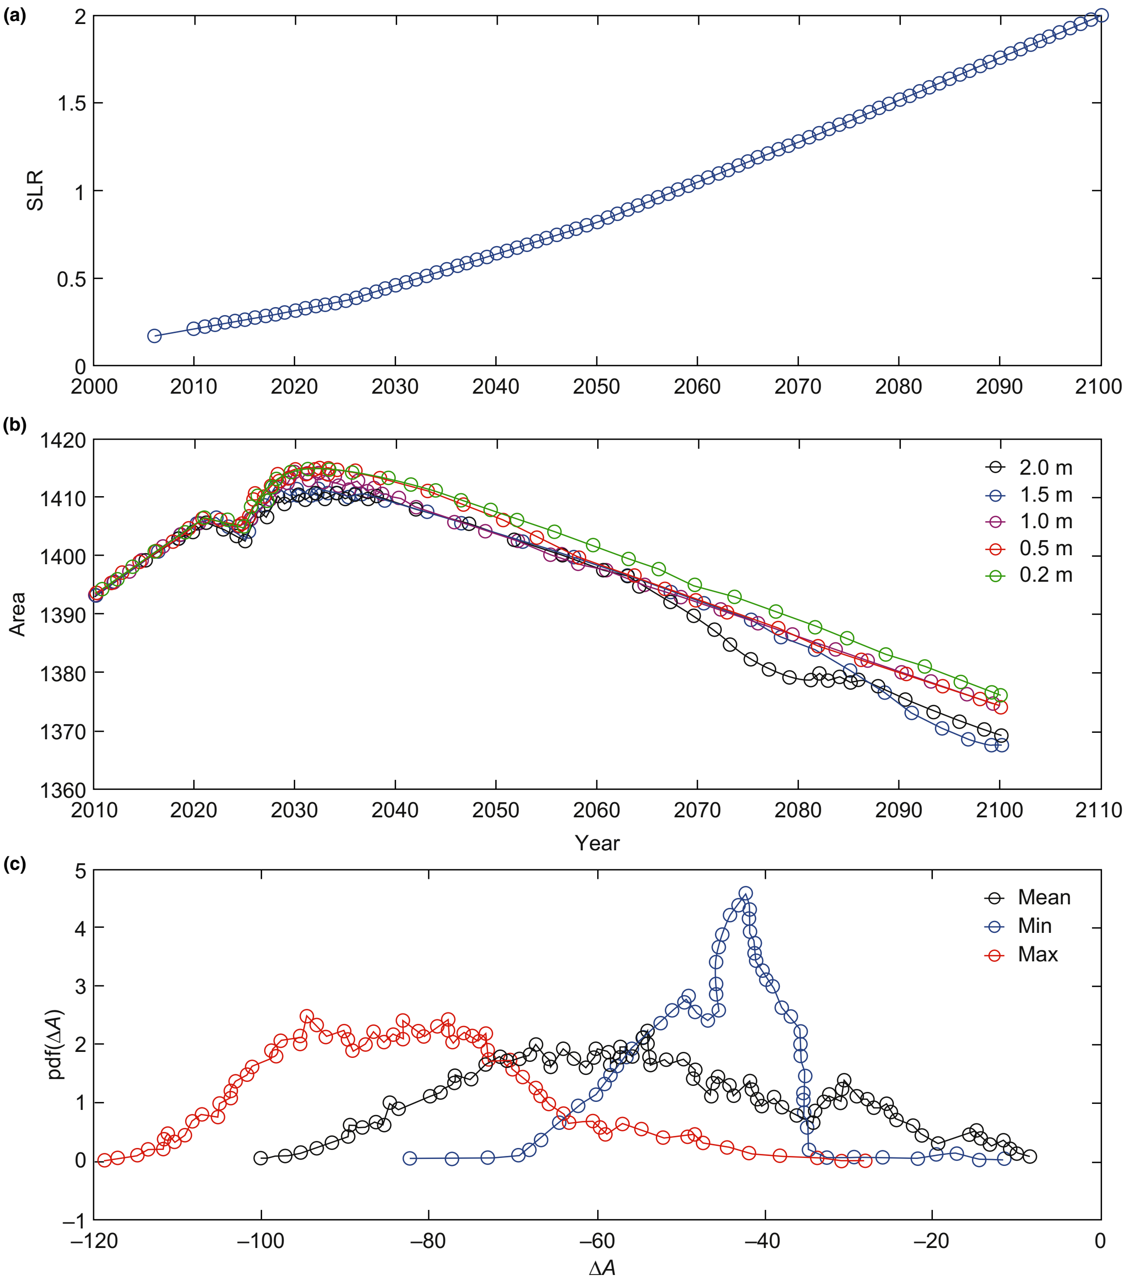

Figure 12 Sea level rise (SLR) curve and prediction of habitat for Santa Rosa Island. (a) IPCC A1B SLR curve rescaled to 2 m in year 2100 in the model simulation. (b) Changes in the area of the beach habitat (ha) consists of estuarine beach, tidal flat, and ocean beach for Santa Rosa Island at different SLR scenarios ((0.2; 2.0) m) (Linkov et al. 2010). (c) Global uncertainty analysis for the beach habitat of Santa Rosa Island (portion managed by Eglin AFB) considering the minimum, mean, and maximum SLR scenarios in the year 2100 in the model simulation (12.9, 38.7, and 69.4 cm, respectively) (Chu-Agor et al. 2011a). ΔA is the change of beach area in hectares.

sedimentation (Linkov et al. 2010; Chu-Agor et al. 2011a). For lower elevation wetlands (salt marsh, tidal flat, and beach), the variance in the output was mostly driven by varying percentages of the DEM vertical error for the lower elevation range zone (0–1 m), historic trend in SLR, salt marsh vertical accretion, and beach/tidal flat sedimentation rate, with the last two factors outweighing the others.

Figure 12(c) shows the results after global uncertainty analysis for the beach habitat of Santa Rosa Island (the portion managed by Eglin AFB), considering the minimum, mean, and maximum SLR scenario for 2100. ΔA is the predicted change in area that shows a quite broad distribution considering the uncertainty of all the input factors. To account for the variation in estimates of SLR, SLAMM simulated the habitat using minimum, average, and maximum SLR according to the IPCC A1B scenario in 2100, that is, 12.9, 38.7, and 69.4 cm, respectively.

GSUA was also applied to the habitat model (MaxEnt) (Convertino et al. 2011) and to the metapopulation model

(RAMAS) (Chu-Agor et al. 2011b) used in the Florida case study. Here, we focus our attention only on the land-cover model that produced predictions of how 'flooding' due to SLR drives the coastal wetland evolution in Florida. The GSUA revealed the dominant input factors, the complete set of scenarios for the habitat quality (from MaxEnt), and the abundance of species (from RAMAS). Thus, GSUA proved to be an extremely useful approach to evaluate the uncertainty of climate predictions – land-cover, habitat quality, and species abundance – and their most important drivers.

5.18.4 Conclusions and Perspectives

The high severity and increasing frequency of major flood events worldwide has driven flooding up the political and risk management agenda (Harvard Business School 2007). In this chapter, we compared the flooding phenomena in two very different complex coastal ecosystems as 'epitomes': Venice and the Gulf coast of Florida. These two coastal ecosystems are complex socioecological systems, and the impact of climate affects differently their natural and human components. The anthropic effect on and regulation of these ecosystems is very different; however, we focused our attention on the correlations between climatological and hydrological phenomena (flooding phenomena) and their effects on geomorphological, ecological, and socioeconomical resources. We used historical data and outputs of climatological models (ERA-40) for Venice to evaluate the drivers of flooding phenomena and the reliability of models to represent historical events. For Florida, we also run models (land-cover, habitat, and metapopulation models) to predict the future effect of SLR on coastal wetlands and shoreline-dependent birds. With our case studies we supported the idea of 'contextual vulnerability' (vs. 'outcome vulnerability') (Pielke et al. 2011) for which threats from climate need first to be considered in terms of historical observations, paleo records, and, in the worst case, sequence of events records. Estimates from the IPCC projections can then be added to the modeling part of the study to determine if climate is predicted by those models to elevate these risks. However, projections should only be performed after the historical climate evaluations are first completed. For example, the historical analysis for Venice confirmed the decreased frequency of extreme tides (Troccoli et al. 2011), and for Florida, the increased frequency of the strongest tropical cyclones (Elsner et al. 2008). In both cases, climate projections conformed to the observed historical trends; however, this may not be the case for other geographical areas or for other climatological phenomena.

The following conclusions are worth mentioning:

- Analyzing the 'high water' phenomena in Venice in 1966, 1986, 1992, and 2000, we found evidence of recurrent correlations between the MSLP gradient (Otranto–Venice), wind velocity, and meteorological tidal level. Considering the historical data in Venice, to negative peak pressure corresponds a positive peak of wind velocity and tidal level. This concurrence of events resulted in exceptional storm surge and flooding events in the city. We found that for MSLP, observed and ERA-40 values are in agreement, while for wind velocity, ERA-40 overestimates or underestimates the observed values.
- We predicted the change of the whole Gulf of Mexico Florida coastal ecosystem considering different SLR scenarios to 2100. We considered in particular the Santa Rosa Island along the north coast of Florida, which hosts 20% of the Snowy Plover population. As expected, the beach habitat posted an increase in area gained from the losses in higher elevation habitats (most probably marshes). For the first 30 years (2010–40), the beach is expected to increase. However, from 2050 forward, the area will decrease gradually until the end of the century, posting a net gain of 2.0% (54 ha). Surprisingly, different SLR projections have the same effects on the beach habitat.
- Careful data analysis is needed to disregard (or support) a priori assumptions such as negative effects of tropical cyclones on species and the increasing 'high water' phenomena in Venice due to SLR. For Florida, a positive/negative feedback has been found between the probability of presence/absence of a nesting ground and tropical cyclone/renourishment events, respectively. For Venice, recent analysis showed that regardless of the persistency of the pressure gradient Otranto–Venice, the frequency of extreme storm surge events affecting the city is going to decrease, and the frequency of extreme tides in Venice might largely remain unaltered if the projected twenty-first century climate simulations are correct (Troccoli et al. 2011). In addition, through a trend assessment based on tidal observations, Troccoli et al. (2011) found a reduction in extreme tidal levels.
- A GSUA was performed for SLAMM for the Santa Rosa Island (Eglin AFB) in Florida. The most important processes involved in the fate of the coastal habitat are different for high- and low-elevation wetlands: inundation and accretion/sedimentation for the former; elevation error, historic trend in SLR, salt marsh vertical accretion, and beach/tidal flat sedimentation rate for the latter. Simulating the IPCC A1B scenario for minimum, average, and maximum SLR, we calculated the probability of change in the beach area, considering the uncertainty of all the input factors. The distribution is quite broad; however, in all the three cases, the beach habitat is subjected to a net reduction, thus enforcing the negative effect of SLR on the Eglin coastal area. GSUA methods are thus extremely useful to assess all the possible states of ecosystems due to climate, which can aid efficient conservation actions.
- SLR studies show the importance of a correct representation of the coastal landform elevation and calculation of the water depth as a function of elevation and infrastructures. Two-dimensional flood modeling supported by vector maps, and integrated to geomorphological and land-cover models, will increase the accuracy of sea level predictions, both on urbanized and natural components of coastal ecosystems. Thus, this will increase the accuracy of predictions and possibly reduce their uncertainty.

Acknowledgments

5.19.1 Introduction

Changes in climatic conditions have been evident over West Africa in the past decades. Decrease in rainfall amount led to severe droughts during the 1970s and 1980s. There has been a shift of the climatic zones in a southerly direction. Consequently, most of the Volta Basin in Burkina Faso is now located in the Sahelian and Sudano-Sahelian zones. As a consequence of instability in the rainfall pattern, many rivers have dried up, large tracts of land cover have been degraded, and the water table is drawing down.

It has been estimated that 340 km^3 of rain must fall on the catchment before runoff occurs at significant levels. This indicates that small changes in rainfall could have dramatic effects on runoff rates. For instance, a rainfall decreased by only 5% from 1936 to 1998 resulted in a runoff decrease by 14% (Andreini et al. 2000). Hydropower dams such as that in Akosombo are therefore vulnerable to even small long-term exclusions of rainfall and, by extension, all socioeconomic activities and already climatic-stressed or water-sensitive ecological systems dependent on these projects.

Extreme droughts cause severe land degradation and crop failures. High rainfall that leads to flooding can destroy crops and infrastructure. The unpredictability associated with rains could lead to high risk in agriculture investments and other water-related livelihoods.

5.19.2 The Volta River Basin: Physical Setting

The Volta River Basin is located in West Africa and covers an area of about 400 000 km^2 of the subhumid and semiarid savannah zone. The north–south extents of this transboundary basin are approximately latitude 5° 30′ N in Ghana to 14° 30′ N in Mali. The widest part stretches approximately from longitude 5° 30′ W to 2° 00′ E. The Basin meets the sea at the Gulf of Guinea in Ghana. It stretches across large proportions of Ghana (70%) and Burkina Faso (63%) and lesser proportions of Togo, Benin, Mali, and Cote d'Ivoire. The proportions of the Volta Basin located within the six West African countries are 43% in Burkina Faso; 42% in Ghana; and 15% in Togo, Benin, Cote d'Ivoire, and Mali (Figure 1).

5.19.2.1 Relief

The basin is flanked by a mountain chain on its west. From the sea and northeastwards rise the Akwapim ranges, followed by the Togo Mountain, Fazao Mountain, and Atakora ranges in Benin. The Kwahu plateau branches northwestwards after the Akosombo Gorge. The only other significant relief on the western part of the basin is the plateau of Banfora. The basin in general has a low relief, with altitudes varying between 1 and 920 m. The mean altitude of the basin is ∼257 m, with more than half the basin in the range of 200–300 m (Moniod et al. 1977).

5.19.2.2 Geology of the Basin

The geology of the main Volta Basin is dominated by the Voltaian system, which lies mainly to the west. This consists of Precambrian to Paleozoic sandstones, shales, and conglomerates. The Buem formation is another geological formation of the main Volta Basin. This series lies between the Togo series, which is to the east, and the Voltaian formation situated in the western part of the Volta Basin (Ministry of Works and Hou 1998). The Togo series and Dahomeyan and Tertiary-to-Recent formations make up the remaining geological formations of the main Volta Basin. Unlike the Voltaian system, the Buem series comprise calcareous, argillaceous, sandy, and ferruginous shales, sandstones, arkose, greywacke, tuffs, and jaspers. The Togo series on the other hand consists of alternating arenaceous and argillaceous sediments and lie toward the eastern and southern parts of the main Volta Basin. The Dahomeyan system, which consists of mainly metamorphic rocks, including hornblende and biotite, gneisses, magmatites, granulites, and schist, is generally found at the southern part of the main Volta Basin.

The Voltaian system, the Buem formation, and the Togo series constitute the major geological formations of the Oti River Basin. The White Volta Basin on the other hand has the Birimian system and the Tarkwaian formation, with the Birimian system consisting of metamorphosed lavae, pyroclastic rocks, phyllites, schists, tuffs, and greywackes. Associated with the Tarkwaian formation are quartzites, phyllites, grits, conglomerates, and schists (Figure 2).

5.19.2.3 Drainage Network and Sub-Basins

Surface water is received from both outside and within the country. Approximately 54% of the flows of the tributaries originate from outside the country. However, in 1970, it was estimated to be around 70%. The apparent reduced contribution may be due to the reduction in rainfall magnitudes in the Sahel since the 1970s (Nicholson 1983). The network of the Volta River System within the territory of Ghana covers about 70% of the total land surface of Ghana. The main subcatchments are the Black Volta, White Volta, and Main/Lower Volta, and Oti and Daka Rivers (Biswas and Obeng).

5.19.2.3.1 The White Volta Basin

The White Volta Basin covers an area of about 49 210 km^2 in Ghana, representing 46% of its total catchment area of 10 741 km^2. The Maorago subcatchment of the White Volta has a total area of 1608 km^2 and stretches across Ghana and Togo. The Tamne subcatchment of the White Volta lies entirely in Ghana. The average annual runoff from the White Volta is about 272 m^3 s^{-1}. The White Volta contributes about 20% of the annual total flows to the Volta Lake.

5.19.2.3.2 The Black Volta Basin

The Black Volta has a total transboundary catchment area of 142 056 km^2. Only 33 302 km^2 (23.5%) of the catchment area is located in Ghana, primarily northwestern Ghana. The annual runoff from the Black Volta Basin is about 243 m^3 s^{-1}. It contributes about 18% of the annual total flows to the Volta Lake.

5.19.2.3.3 The Lower Volta Basin

The lower basin is located below the confluence of the Black Volta and the White Volta Rivers, excluding the Oti River drainage area. The surface water resources consist of flows from outside and within Ghana. The basin covers a total area of about 68 588 km^2, with 50 432 km^2 located in Ghana. The natural total mean runoff from the basin is estimated at 1160 m^3 s^{-1}.

5.19.2.3.4 Oti Basin

The Oti River Basin has an area of 16 801 km^2 in northeastern Ghana, with the remaining located in Togo. The discharge from the Oti Basin is about 10–1270 m^3 s^{-1}. The annual flow from the Oti River Basin contributes about 25% of the annual total flows to the Volta Lake due to the steep topography and the relatively high rainfall within the basin.

5.19.2.3.5 Daka Basin

The Daka Basin covers an area of 7424 km^2 and is located almost entirely in the eastern part of northern Ghana. The annual rainfall in the basin varies between 1120 and 1340 mm. Most of the biophysical characteristics found in the basin are similar to those of the Oti River Basin.

5.19.2.4 Rainfall

Climatic conditions are controlled by two air masses: the northeast trade winds (harmattan) and the southwest trade winds (monsoon). The dry northeast trade winds originate from the interior of the continent, whereas the southwest

trade winds are moist since they blow over the seas. The interphase of these two air masses, the intertropical convergence zone (ITCZ) is associated with a considerable amount of rainfall. The ITCZ moves northwards and southwards across the basin from about March to October, when rainfall is received in the region. More detailed information is given in Section 5.19.5.

Three types of climatic zones are identified in the region: the humid south with two distinct rainy seasons, the tropical transition zone with two seasons of rainfall – very close to each other, and the tropical climate north of latitude 9° N. Average annual rainfall varies across the basin from approximately 1600 mm in the southeastern section of the basin in Ghana to about 360 mm in the northern part of Burkina Faso. The rainfall days decreases in a south–north direction. For instance, in the Sahelian zone the rainy season lasts for about 3 months, whereas there are about 6–7 months of rainfall days in the southern part of the Sudan zone. Dominant winds blow east–west from January to March, which is the harmattan season. Rainfall reduction has been evident since the 1970s (Opoku-Ankomah 2000). Some areas that used to have bimodal type of rainfall have only one mode, as

the second minor season has become very weak or nonexistent (Figure 3).

5.19.2.5 Temperature and Humidity

The annual mean temperatures in the basin vary from about 27–30 °C. Daily temperatures can be as high as 32–44 °C and as low as 15 °C nocturnally. Humidity varies between 6 and 83% depending on the season and the location. Temperatures are higher in the upstream than downstream.

In Ghana, the mean air temperature never falls below 24 °C because of its proximity to the equator. The hottest month of the year is March–April and the coolest is August. The southern section of the country is more humid than the north. In the coastal area of Ghana, the relative humidities are 95–100% in the morning and about 75% in the afternoon. In the north, values can be as low as 20–30% during the harmattan period and 70–80% during the rainy period. The first cool period occurs in December–February, with average maximum temperatures varying between 33 and 35 °C in January and average minimum temperatures in the order of 14 (north), 17 (center), and 19 °C (south). The average maximum and minimum temperatures during this cool period are subject to extreme variations because of the irregularity of the rains (Figure 4).

Figure 4 Spatial distribution of temperature in Volta Basin.

5.19.2.6 Evaporation and Evapotranspiration

Evaporation in the basin is relatively high, especially in the Sahelian zone. In Burkina Faso, the lowest record is about 1900 mm per annum. In the Volta Basin of Ghana, potential evapotranspiration varies from a minimum of 1450 mm per annum in the Black Volta subbasin to a maximum of 1968 mm per annum in the White Volta subbasin. Panevaporation is the same (2540 mm per annum) in all the sub-basins except the lower basin. In Burkina Faso, average annual panevaporation values are generally very high and progressively increase from south to north (Figures 5 and 6).

5.19.3 Surface Water Sources and Quality in the Volta System

Although some historical data was available for all the rivers in the Volta Basin, these varied greatly in terms of period and time when they were studied. The mean results of the physico-chemical analysis of samples collected from several stations give an indication of the quality of the river systems. Sampling stations were located on tributaries of the Volta as well as the main lake; the data is therefore fairly representative of the quality of the entire lake.

5.19.3.1 Thermal Changes in the Volta Lake

Significant thermal changes were observed in the main Volta Lake, near Akosombo, during the early stages of filling, between 1964 and 1966. As the lake filled, Biswas (1968) described appreciable differences between the surface and the bottom. The mean temperatures for all the data collected were 29.09 °C for the surface and 26.97 °C for the bottom. Major changes in the surface and bottom temperatures are presented in Table 1. Temperatures in both locations experienced considerable undulating rises and falls over the period of study. The surface temperature decreased significantly from June to August 1964. It then increased gradually from September 1964 and peaked in May 1965; thereafter, there was a rapid decrease, reaching a low point in August 1965. This was followed by a general rise, resulting in a peak in April 1966.

The bottom temperature also decreased significantly from June to August 1964. It continued decreasing and reached its lowest in October 1964, then rose gradually until July 1965, and maintained an average of 27.24 until March 1966. Five years later (1971), intensive studies carried out by the Government of Ghana showed that both the surface temperature (29 °C) and the bottom temperature (27 °C) did not vary much.

5.19.3.2 Other Physicochemical Parameters

Early studies carried out by Entz (1968) between 1965 and 1966 showed that the lake was chemically oligotrophic, with

low levels of parameters such as HCO_3^-, Ca^{2+}, Mg^{2+}, Na^+, total Fe, NO_2^- and PO_4^-, among others.

Iron (II) and chloride were, however, high in some tributaries like the Dayi. Within this period, no remarkable limnological changes took place within the upper 5-m layer of the Volta Lake. More extensive studies carried out later by Andah et al. (2003) on ADAPT (adaptations strategies to changing environments in the Volta Basin) Volta project for these parameters (Table 2) indicated slightly elevated levels over those recorded by Entz (1968). Andah et al. between 1976 and 1978 recorded physicochemical measurements that included transparency (which varied from 400 cm in the main lake to 30 cm in the north during the flood period), pH, alkalinity, phosphate, nitrate, ammonia, iron, silica, calcium, magnesium, potassium, sodium, and hydrogen sulphide.

Nutrient content of the Volta Lake is low compared to other tropical lakes, but high concentrations occurred during flood, under conditions of strong mixing. The Afram arm recorded the least nutrient content as compared to the other tributaries; for instance, ammonium concentration ranged from 0.02 to 0.04 mg l^{-1} at all levels except at the bottoms, where sometimes values as high as 5.20 mg l^{-1} were registered. The nitrite form was not detected at all, except, occasionally at the very bottom where values scarcely reached 0.01 mg l^{-1}. The nitrate form on the other hand was always present but in low values ranging between 0.01 and 0.03 mg l^{-1} (Obeng-Asamoah 1977).

Table 1 Monthly mean of surface and bottom temperatures (°C) of Volta Lake at Akosombo (Ajena)

Month	*Surface: 1964–65*	*Surface: 1965–66*	*Bottom: 1964–65*	*Bottom: 1965–66*

Source: Biswas, E. R. I. 1968: Thermal changes in the Volta Lake in Ajena. *Man-Made Lakes.* L. E. Obeng, Ed., Ghana Academy of Sciences, 103–109.

The pH ranged in the northern sections of the lake between 6.8 and 7.4 at the surface and stabilized at 6.7 at the bottom. In the south, the pH on the surface ranged from 7.8 to 8.5. The inflowing tributaries were observed to sometimes have higher pH values. Free carbon dioxide followed the normal pattern, mostly increasing toward the bottom following the decrease of oxygen. In the thermocline or whenever the dissolved oxygen (DO) content drops to zero, an increase in free carbon dioxide followed.

Marked differences in total alkalinity of water were found between the upper and lower reaches of the Volta River before the dam was built. This also applied to the smaller and larger tributaries. After the dam was built, the differences were nearly equalized, and there was hardly any change from north to south. The content ranged between 19 and 41 mg $CaCO_3$ in the open lake, was 50 mg l^{-1} in the Sene River, and was up to 60 mg l^{-1} in the Afram arm. In general, the alkalinity of the Volta Lake was very low. Iron was mostly detected in the surface water layers in the north. In the south it was found only in the hypolimnion but in higher concentrations. The distribution of orthophosphates in the lake was similar to that of iron. Phosphates were recorded at all depths in relatively high concentrations (up to 0.5 mg l^{-1}) in the north, where it is possibly brought in by the Black and White Voltas.

In all other parts of the lake, orthophosphate was sometimes not detectable in the epilimnion, especially after long periods of stagnation. In all probability the lack of phosphorus prevented an improvement of primary production in the main lake. The same pattern existed for nitrate-nitrogen. In the northern regions as well as the upper parts of the tributaries, the amounts were quite high and had the tendency to decrease toward the south. However, as soon as a water bloom of phytoplankton appears, this nutrient depletes almost entirely in the surface layers. Nitrate-nitrogen was not necessarily a limiting factor in phytoplankton production in the lake, as it might be in other lakes. Ammonia was mostly present in the hypolimnion where it accumulated during the stagnation period, similar to iron and phosphates.

Silica was always available in sufficient quantities, between 12 and 25 mg l^{-1} SiO_3 in the main lake, and up to 27 mg l^{-1} in the upper Afram for diatom production. Calcium and magnesium were uniform in vertical as well as in horizontal distributions and ranged mostly under 10 mg l^{-1} Ca and 5 mg l^{-1} Mg. The same can be said for potassium and sodium, which had low values. Conductivity ranged from 63 μS cm^{-1} in the north up to 172 μS cm^{-1} at Kete Krachi. The differences between the surface and the bottom were very little. A study by Amoah and Koranteng (Amoah and Koranteng 2008) from 1996 to 2006 in the lower Volta indicates that parameters such as surface temperature, pH, conductivity, and nitrate-nitrogen did not change much. However, there has been a remarkable increase in the levels of other parameters such as total hardness and chloride (Table 3). Similarly, a recent study (Abdul-Razak et al. 2009) on the Oti River indicates deterioration in parameters such as pH, and nitrate-nitrogen, DO, and

bacteriological content, while other physicochemical parameters did not vary much.

5.19.3.3 Bacteriological Quality

Data on the bacteriological quality of Volta Lake covering the period of filling is virtually absent. Initial studies during the formation period carried out by Biswas (1968), 1 km from the dam site, showed that bacteria counts were higher at the surface and decreased with depth (Table 4). However, post-impoundment studies carried out by Amoah (1999) at 10 years interval, 1977 and 1987, both within the main lake around Akosombo and along the Afram tributary showed increase in bacterial population with depth in contrast to Biswas (1968); the deeper parts, 20 m and below, supported higher counts, with two peaks coinciding with the major and minor rainy seasons.

5.19.4 Groundwater Sources in the Volta Basin of Ghana

5.19.4.1 Hydrogeology

Three major hydrogeologic systems govern groundwater resource availability in Ghana. These include the basement complex composed mainly of Precambrian crystalline igneous and metamorphic rocks and the Paleozoic consolidated sedimentary formations. The basement complex constitutes about 54% of the geological formation of the country. It is made up of a wide variety of Precambrian igneous and metamorphic rocks. Generally, the basement complex consists of gneiss, phyllite, schist, mihnatite, granitegneiss, and quartzite. On the basis of geology and groundwater conditions, this can further be divided into subregions. These subregions include the metamorphosed and folded rocks of the Birimian system, the Dahomeyan system, the Tarkwaian system, the Togo series, and the Buem formation. Groundwater occurrence in this complex is associated with secondary porosity resulting from jointing, shearing, fracturing, and weathering. This is on account of the fact that the underlying rocks of the basin are essentially impermeable and have very little or no inherent porosity.

[b] Amoah, C. M., 1999: Overview of microbiological studies on the Volta Lake. *The Sustainable Integrated Development of the Volta Basin in Ghana.* C. Gordon and J. K. Amatekpor, Eds., Volta Basin Research Project, 33–3.

The second geological formation associated with groundwater resources in Ghana is the Paleozoic consolidated sedimentary formations. Locally referred to as the Voltaian formation it underlies about 45% of the country and consists mainly of sandstone, shale, arkose, mudstone, sandy and pebbly beds, and limestone. This formation is further subdivided into Upper Voltaian, Middle Voltaian, and Lower Voltaian on the basis of lithology and field relationships. The Upper Voltaian formation consists of massive sandstone and thin-bedded sandstone, with the Middle Voltaian formations having the Obusum and Oti Beds.

Mesozoic and Cenozoic sediments make up the remaining 1% of the rock formation and are found in two coastal provinces. These are the Block-Fault and the Coastal Plain Provinces and the Alluvial Province. The coastal Block-Fault Province consists of a narrow discontinuous belt of Devonian and Jurassic sedimentary rocks that have been broken into numerous fault blocks and are transacted by minor intrusion. The Coastal Plain hydrogeologic province on the other hand is underlain by semiconsolidated to unconsolidated sediments. These range from Cretaceous to Holocene in age and could be found on the southeastern part of Ghana, in a relatively small isolated area in the extreme south of the western part of the country. Narrow bands of alluvium of Quaternary age, occurring mainly adjacent to the Volta River and its major tributaries and in the Volta delta form the majority of the alluvial hydrogeologic province (Moniod et al. 1977; Dapaah-Siakwan and Gyau-Boakye 2000; Acheampong and Hess 1998).

5.19.4.2 Aquifers in Ghana

Groundwater flow patterns and recharge systems in Ghana have generally not been very easy to gauge properly, because of the complexity of the terrain (Community Water and Sanitation Agency 2001). Generally, the basement complex and the Voltaian formation, which underlie about 99% of the country, are impermeable and, thus, have no inherent porosity. Groundwater occurrence in these formations is therefore associated with the development of secondary porosity resulting from jointing, shearing, fracturing, and weathering. Two main types of aquifers are therefore identified, namely, weathered zone aquifers and fractured zone aquifers (Acquah 2002).

The weathered zone aquifers occur mostly at the base section of the thick weathered layer and vary from outcrops to about 100 m depth. It is thickest in the wet forested southwestern part of the country where it reaches an average thickness of about 60 m depth. The weathered layer is very thin at the semiarid zone of the extreme northeast where the average thickness is about 10 m. The fractured zone aquifers on the other hand are discontinuous and limited in area. Groundwater occurs mostly under semiconfined or leaky conditions because of the sandy clay nature of the weathered overburden, and yields rarely exceed 6 $m^3 h^{-1}$.

Aquifers occurring in the remaining 1% of the formations in Ghana are confined mainly to the extreme southeastern and western parts of the country and are associated with the Cenozoic and Mesozoic sediment formations. One aquifer occurs in the resent sand, which is very close to the coast. The aquifer, which is unconfined, is located at a depth of between 2 and 4 m and contains fresh meteoric water. An intermediate aquifer that is either confined or semiconfined occurs mainly in the red continental deposits of sandy clay and gravel. This aquifer varies in depth from 6 to 120 m and contains mostly saline water. A third type of aquifer could be located at depths of between 120 and 300 . This type of aquifer is often referred to as limestone aquifer. With an average yield of about 148 $m^3 h^{-1}$, the groundwater in this aquifer is fresh and occurs under artesian conditions.

Owing to lithological variables and structural complexes of the rocks, yields from boreholes in the various geological formations are variable. Studies conducted by the Water Resources Research Institute in Ghana on borehole yields indicate average yields that vary widely, ranging from about 3.0 to 12.7 $m^3 h^{-1}$ in the basement complex, about 8.5 $m^3 h^{-1}$ in the Voltaian formation, and in a range of 4.0 to about 11.7 $m^3 h^{-1}$ within the Mesozoic and Cenozoic formations (Acheampong and Hess 1998).

Information on groundwater recharge in Ghana is very scanty, although recharge of most of the aquifer systems in Ghana is thought to be by direct infiltration of precipitation through fault zones and fractures along the highland fronts and also through the sandy portions of the weathered zone. Substantial amounts of recharge are also thought to occur through seepage from ephemeral stream channels during the rainy seasons. In addition, some indirect recharge mainly occurs in the lower rainfall, low-relief, and low-permeability areas, especially, when runoff from watershed outside the areas or a particular storm event is of sufficient magnitude to cause runoff. This is made possible when drainage courses or streams that act as conduits for the overland flows allow a greater part of the runoff to infiltrate through their beds to the groundwater table on account of their generally weak fissured zones.

Studies conducted by some researchers in Ghana over the years indicate that the quality of groundwater in Ghana is generally good for multipurpose use (Kortatsi 1994; Moniod et al. 1977; Andah 1993; FAO 1996).

For both human consumption and irrigation, groundwater is globally regarded as a very important resource. The occurrence of groundwater in Ghana is associated with the three main geological formations of the Volta Basin. These include the basement complex made up of crystalline igneous and metamorphic rocks.

5.19.5 Agroecological Zones in the Volta Basin of Ghana

An agroecological zone is a land resource mapping unit defined in terms of climate, landform and soils, and/or land cover, which has a specific range of potentials and constraints for land use (Barry et al. 2005).

In Ghana, six major agroecological zones are recognized. These zones are defined by climatic and edaphic factors and reflected in the distinctiveness of the associated natural vegetation. There is a vicious gradation from forest to grassland as one moves from the lower latitudes in the south to the higher ones in the north. The zones consist of the high rainforest zone, the semideciduous forest (SDF) zone, the forest–savanna transitional zone, the guinea savanna zone, the Sudan savanna zone, and the coastal savanna zone. There are considerable variations between successive rainy seasons in terms of the onset, duration, and amount of fall. Rainfall within the agroecological zones is generally accompanied by high intensities and energy loads and is therefore erosive. Generally, alluvia soils (Fluvisols) and eroded and shallow soils (Leptosols) are found in all the agroecological zones (Obuobie and Barry 2010; Amatekpor 1997).

The Volta Basin, which occupies approximately two-thirds of Ghana, transcends five of the six major zones, excluding the high rainforest zone, which is located at the extreme southwestern corner of the country. In addition, mangrove swamps are found, albeit in patches along the entire Volta Basin coastline and beyond (Gyasi and Enu-Kwesi 1997). The basin, therefore, encompasses a wide diversity of floral and faunal species in line with the variety of ecological zones. The zones have, however, undergone tremendous changes as a result of anthropogenic forces induced by population and production pressures (EPA 2002). Pristine vegetation is almost absent apart from a few protected areas, steep slopes, and river courses within the basin.

5.19.5.1 Coastal Savanna Zone

The costal savanna zone in Ghana covers an estimated area of 4500 km^2. Rainfall in the zone is bimodal, varying between 600 and 900 mm, with an annual average of about 810 mm. The major rainy season occurs from March to mid-July, with a peak fall in June. The minor rainy season starts in early September and ends at the beginning of November. The major dry season occurs between mid-November and end of February (Gordon et al. 2003). The mean annual maximum and minimum temperatures are 30.5 and 22.9 °C, respectively. Relative humidity varies from 55 to 65% during the day and falls to about 40% during the major dry season (Obuobie and Barry 2010). In terms of averages, the annual aridity index averages about 0.54, whereas the average wind speed is 251 km day. The average sunshine hours and solar radiation are 6.5 h and 18.6 $MJ\,m^{-2}\,day^{-1}$, respectively. Annual potential evaporation is about 1504 mm (Gordon et al. 2003).

The vegetation consists mainly of grassland interspersed with dense short thickets often less than 5 m high with a few trees such as *Antiaris africana*, *Ceiba pentandra*, *Milicia excelsa*, *Albizia zygi*, and *Azadirachta indica*. Short and medium grasses are the dominant plant species, notable among which are *Andropogon gayanus* and *Hyparrhenia dissolute* in upland areas and *Vetiveria fulbibarbis*, *Brachiaria falcifera*, and *Bothriochloa bladhii* in low-lying areas.

The dominant soils of the zone include Acrisols, Cambisols, Gleysols, Luvisols, Solonetz, Vertisols, and intergrades (Obuobie and Barry 2010).

Within the Volta Basin, the coastal zone extends about 2 km off the estuary to about 80 km upstream, forming the area referred to as the Lower Volta Basin. Important towns within the zone include Akuse, Aveyime, Bator, Mepe, Adidome, Sogakope, Big Ada, and Dabala (EPA 2002).

5.19.5.2 Mangrove Ecosystem

Mangrove ecosystems are limited to a very narrow, noncontinuous coastal area around lagoons and on the fringes of the Volta River estuary. The ecosystem consists of water, muddy soil, trees, shrubs, and their associated flora, fauna, and microbes. Together with the associated wetlands, they provide habitat for high concentrations of birds, mammals, reptiles, amphibians, fish, and invertebrate species. In Ghana, the mangrove forest covers a total area of about 100 km^2, but it is much more limited in the Volta Basin where activities of local people continue to degrade the ecosystem (Finlayson et al. 1998). This area serves as a nursery site for commercial marine fishes and shrimps and is known globally as a significant habitat for migrating birds. As a result of the ecological wealth of this zone, the Keta and the Songhor Lagoons, which form integral parts of the zone, have been designated as Ramsar sites (Rubin et al. 1998).

The most common mangrove species found in Ghana are *Rhizophora racemosa*, *Avicennia nitida*, and *Drepanocarpus lunatus* (a climber). The combined effects of human activities and cessation of annual flooding within the lower reaches of the Volta has resulted in an increase in the abundance of weeds, particularly the bulrush *Typha domingensis* (*T. australis*), the fern *Acrostichum aureum*, rhizomatous grass *Paspalum vaginatum*, club rush *Cyperus articulatus*, and two spreading, succulent herbs, *Sesuvium portulacastrum* and *Philoxerus vermicularis* (Boko et al. 2007).

Mangroves have the potential to curtail the adverse effects of flooding associated with sea level rise especially in the event of climatic change. As Boko et al. (2007) state, the projection of sea level rise could, among other things, increase flooding and increase the high socioeconomic and physical vulnerability of coastal cities. Mangrove ecosystems conservation should therefore be a collective responsibility, with a high degree of local involvement.

5.19.5.3 The Semideciduous Forest

The SDF zone in Ghana is located above the high forest zone and has an aerial extent of about 66 300 km^2. It covers a very extensive area, constituting about 90% of the total forest zone. The zone is characterized by a bimodal rainfall distribution pattern, with mean annual totals ranging from 1400 to 1750 mm. Temperatures are generally high throughout the year. The mean annual temperature is about 27 °C, with an annual mean variation of 31 and 20.6 °C in the hottest and coolest months, respectively. The relative humidity could be as high as 90% in the mornings and during the wet seasons but falls below 80% during the dry seasons. The potential evapotranspiration is about 1350 mm year^{-1} (Obuobie and Barry 2010).

The associated trees in the SDF include *Afzelia africana*, *Albizia adianthifolia*, *C. pentandra*, *Cola caricifolia*, *Cola gigantea*, *Diospyros mespiliformis*, *Elaeis guineensis*, *Malacantha alnifolia*, *Sterculia tragacantha*, *Anchomanes* sp., *A. africana* and *Chlorophora excelsa*. A major characteristic feature of the SDF is that the trees shed their leaves during the dry season (Obuobie and Barry 2010).

The zone supports most of Ghana's food crops, such as maize, cassava, and plantain, as well as major commercial crops, namely, cocoa and oil palm. In addition, most of the timber for both local consumption and export comes from the zone. Soils present in this zone are Acrisols, Nitrisols, and Gleysols (Obuobie and Barry 2010).

The SDF zone is not very extensive, as the Volta, within this zone, flows between two mountain ranges before crossing the gorge where the Akosombo dam was created, thus making the basin very narrow. In addition, the SDF zone by itself is very extensive in the western part of the country but narrows up toward the east where the basin is to be found. The zone covers parts of the Eastern, Ashanti, Brong Ahafo, and Volta Regions. Crop cultivation is not widespread within the gorge area, as farming is prohibited here for strategic reasons. Elsewhere major crops including all the aforementioned are extensively cultivated.

5.19.5.4 The Forest–Savanna Transitional Zone (Derived Savanna)

The forest–savanna transition zone covers about 8300 km^2. It is located above the SDF zone and extends across the entire middle belt zone of the country. The zone is also characterized by two rainfall maxima regimes, with mean annual totals ranging from 1200 to 1400 mm. Temperatures are on average high with an annual mean of about 26.5 °C. Morning and midday relative humidity values range between 85 and 88% and 70 and 74%, respectively. Potential evapotranspiration in this zone is about 1350 mm year^{-1} (Obuobie and Barry 2010).

The zone contains a mix of both savanna and forest tree species, with most of them shedding their leaves during the dry season. Species such as *Daniella oliveri*, *Borassus aethiopum*, and *Terminalia macroptera* also occur. These trees occur in association with tall to medium grass such as andropogon and *Pennisetum* spp. The soil types here are Lixisols, Nitrisols, Plinthosols, and Cambisols (Obuobie and Barry 2010).

This zone is the second largest agroecological zone within the basin after the guinea savanna zone. It covers the Afram Plains portion of the eastern and Ashanti Regions, the mid and northern portions of the Volta Region, and parts of the Brong Ahafo Region. Major crops cultivated in this zone include maize, yam, cassava, groundnuts, and cowpeas. The area is also extensively grazed by cattle (Gyasi 1997; Nsia-Gyabaah et al. 1994).

5.19.5.5 Guinea Savanna Zone

The guinea savanna zone has an aerial extent of about 147 900 km^2 and is by far the largest agroecological zone in the country. This zone is characterized by a single maxima rainfall regime, which begins from April and ends in October. The mean annual rainfall varies between 1000 and 1200 mm. The dry season is experienced within the months of November to March when the desiccating effect of the harmattan that blows across the Sahara Desert is strongly felt. The mean annual temperature ranges between 27.8 and 28.5 °C. Compared to the forest zone, the guinea savanna has a wide range of temperatures, with the highest annual mean ranging between 33 and 35 °C and the lowest annual mean of about 22 °C. The relative humidity of the zone is about 40% in the dry season but may reach 84% in August, the peak of the rainy season. Potential evapotranspiration is very high and varies between 2000 and 2300 mm year^{-1} (Obuobie and Barry 2010).

The associated vegetation consists typically of grasses of varying heights interspersed with fire resistant, deciduous, broad-leaved, and gnarled trees at the forest margins in the south. Toward the north, the vegetation grades into a more open grassland with widely spaced shorter trees. The grasses dry up during the dry season and are usually burnt by illegal herders and hunters. The most common grass species include *A. gayanus*, *Heteropogon* spp. and *Cymbopogo gigantus*. *Vetiveria nigritana*, *Seteria anceps*, and sedges also occur in alluvial sites. The common tree species include *Lophira lanceolata*, *Anogeissus* spp., *A. africana*, *Prosopis africana*, *Pterocarpus erinaceus*, *Parkia clappertoniana*, *Butyrospermum parkii*, and *A. africana*. Fringe forests and woodlands may be found along the watercourses. Soils present in this zone are Lixisols, Acrisols, Luvisols, and Gleysols (Obuobie and Barry 2010).

The guinea savanna agroecological zone spans about two-thirds of the Volta Basin, covering northern parts of the Brong Ahafo and the Northern and Upper West Regions. The zone also covers the greater part of the Upper East Region save for the northeastern corner where the Sudan Savanna is found. Intense human activities including farming, logging, fuel wood extraction, and bush burning within this zone make it very vulnerable and susceptible to flooding and other extreme events (Biney 1990). Crops cultivated here include maize, sorghum, yam, groundnuts, millet, beans, and cowpeas.

5.19.5.6 Sudan Savanna Zone

The last agroecological zone of the Volta Basin within Ghana is the Sudan savanna zone. It extends into Ivory Coast and Burkina Faso to the west and north, respectively, and covers an estimated area of 1900 km^2. It is also characterized by a single rainfall maxima regime and experiences annual average rainfall varying between 900 and 1000 mm. Mean annual maximum temperature ranges from 27.8 to 28.5 °C. Relative humidity is about 40% in the dry season but may reach 84% in August, just as the in the guinea savanna zone. Potential evapotranspiration is also similar to that of the guinea savanna zone (Obuobie and Barry 2010).

The vegetation type is open grass with scattered short drought- and fire-resistant deciduous trees. Grass cover is very sparse, and in most areas, the land is bare and severely eroded. The dominant trees in the zone include *Adansonia digitata*, *C. pentandra*, *B. parkii*, *P. clappertoniana*, *Tamarindus indica*, and *Acacia albida*. The soil types here are Lixisols, Acrisols, Luvisols, and Lithosols (Obuobie and Barry 2010).

The Sudan savanna zone within the Volta Basin is limited to a very narrow strip in the northeastern borders of Ghana with Burkina Faso. The zone is susceptible to desertification, and there is the fear that increased human activities could bring this about sooner than later (Biney 1990). The most common crops cultivated include sorghum, millet, maize, groundnuts, and cowpeas (Figure 7).

5.19.6 The History of Development of the Volta Basin

5.19.6.1 Changes in Water Supply and Use

Changes in water supply and use within the Volta Basin reflect changes due to increase in population pressure and use of water for agricultural, industrial, and electricity generating purposes. There has been an increase in the number of large and small dams also as a consequence of increased population pressure.

As a result of the damming of the Volta River at Akosombo, one of the largest manmade lakes in the world has been created, covering an area of approximately 8500 km^2. A smaller and shallower impoundment, the Kpong Headpond, which covers an area of roughly 38 km^2 with a storage capacity of 2000×10^6 m^3, was completed in 1981 when another hydroelectric dam was constructed at Kpong, 20 km downstream of Akosombo (Obuobie and Barry 2010). The construction of the Kpong dam has resulted in near pollution-free water emanating downstream of Akosombo and hence improving the water quality (Ansa-Asare and Asante 1998). Within the West African region, Benin has a hydroelectric power station on the Oti River, with a storage capacity of 350 million m^3 and the capacity to produce 15 MW. In addition, a hydroelectric power station has been planned at Pouya (Natitingou) on the Yeripae.

In Burkina Faso, in recent decades, there has been a push to increase the number of dams in the Volta Basin to meet the country's need and demand for fresh water. As a result, there are now estimates of between 600 and 1400 dams and lakes with a total storage capacity of 4.7 billion m^3 and about 10 484 wells of which 8020 are in good condition (Obuobie and Barry 2010). The volume stored annually in these reservoirs is about 2490 billion m^3. On hydropower, 13 locations have been identified in the country and 10 are located within the Volta Basin. Several planned irrigation projects covering a total area of 1045 ha will require about 65.3 million m^3 according to an estimate (Obuobie and Barry 2010).

5.19.6.2 Hydro-Development

The Akosombo dam in Ghana is the most significant structure built in the Volta Basin, resulting in the formation of the Volta Lake. The seasonal rise and fall is about 2.0–6.0 m, and the areas covered by seasonal fluctuations are about 100 000 ha (Obuobie and Barry 2010). Water available from the Volta Lake reservoir is used primarily for hydro energy production, transportation, fishery, tourism, and irrigation. The Akosombo dam generates 80% of the power produced in Ghana and is of strategic importance to the economy of the country. The primary purpose of the project was to supply cheap electricity to smelt aluminum, and the secondary one is the development of the country.

When the lake was constructed, it led to the resettlement of about 80 000 people from several hundred villages to 50 newly built townships (more than 1% of Ghana's population at that time). In addition to the resettlement of the river communities, damming affected local health, agriculture, fishing, and navigation (Obuobie and Barry 2010).

Several years after the Akosombo dam was built, the Kpong headpond (reservoir) was built in 1981, which created the potential for two industries, agriculture by irrigation and fishing (Vanderpuye 1982). In 1982, for example, the reservoir produced about 463–618 metric tons of fish (GEF-UNEP 2002) and serves as the main source of water supply to the Accra-Tema metropolitan areas of Ghana.

5.19.6.3 Water Institutions and Legislation

Institutions related to water resources management and legislations have evolved to manage the water resources of the Volta, both in relation to its hydroelectric usage and its use for domestic and commercial purposes. Some of the relevant acts for establishing new institutions and strengthening existing ones when it comes to managing water resources in Ghana, and in particular the Volta Basin are as follows:

- Act 46 of 1961 (Volta River Development Act) sets up the Volta River Authority (VRA) with mandate to plan, execute, and manage the development of the Volta River. Subsequent Acts such as Act 490 of 1994 establishes the Environmental Protection Agency (EPA) of Ghana.
- Act 522 of 1996 establishes the Water Resources Commission.

Also, there are institutional structures and legal frameworks established in the riparian countries of the Volta Basin for environmental management and documented by various country reports as summarized in Table 5.

Table 5 Some ministries and departments for managing water and land resources in the Volta Basin

Country	*Ministry*	*Department/Institute*	*Responsibilities*
Benin	Agriculture, livestock, and fishing	Rural development, forest and natural resources, agriculture, fishing, and livestock	Management of natural resources, water, and soil
Benin	Mines, energy, and hydraulics	Mining, Beninois Society of Electricity and Water, and hydraulics	Management of mineral resources, management and distribution of water resources at the national level
Burkina Faso	–	Foreign affairs	Implementation of framework of agreements of international cooperation
Cote d'Ivoire	Mines and energy	–	Generation of hydroelectricity
Cote d'Ivoire	Environment and life	–	Protection of water
Ghana	Works and housing	Water Resources Commission	Planning and regulation of the development and use of freshwater resources in Ghana
Ghana	Environment, science, and technology	Environmental Protection Agency (EPA)	Management of country's environment, collaborating with relevant state institutions and international bodies in ensuring sustainable development of the country's natural resources
Ghana	Energy	Volta River Authority (VRA)	Plan, execute, and manage the development if the Volta River for hydropower generation

Culled from Barry, B., E. Oboubie, M. Andreini, W. Andah, M. Pluquet, 2005: Comprehensive assessment of water management in agriculture. Comparative study of river basin development and management. Draft report to International Water Management Institute and Comprehensive Assessment of Water Management in Agriculture.

5.19.6.4 Policy Frameworks and Water Visions

The water policy of Ghana aims at achieving an efficient and effective management system for the sustainable development of water resources in Ghana to assume full socioeconomic benefits for present and future generations (Obuobie and Barry 2010). This is against the backdrop that water is essential to man and all living things and that health, nutrition, and food production, for example, depend on its availability in adequate quantities and good quality.

Among others, Ghana's water policy is guided by the following:

- The principle of fundamental right of all people to safe and adequate water to meet basic human needs.
- The principle of recognizing water as a finite and vulnerable resource, given its multiple uses and the principle of polluter pays, to serve as a disincentive to uncontrolled discharge of pollutants into the environment.

In line with these principles, steps have been taken in the basin to create a policy environment that promotes sustainable water resource management. The preamble to the water vision recognizes that population increase, rapid urbanization, and industrialization have made water increasingly scarce and often of low or reduced quality (Obuobie and Barry 2010). If regional climate statsitics change so as to increase both the spatial and temporal unpredictability of water availability, to reduce the risk to such a change, the Ghana water vision for 2025 has the main objective to "promote an efficient and effective management system and environmentally sound development of all water resources in Ghana" (Obuobie and Barry 2010).

In line with the water vision, there has been a strategic action plan for the Volta (Andah and Gichuki 2005), with priority areas focusing on the following:

- Policy actions
- Legislative/regulatory reform
- Institutional strengthening
- Capacity building
- Investment
- Scientific investigation
- Data management

An overview of aspects of legal and regulatory interventions needed to achieve environmental quality objective such as a balanced aquatic ecosystem is provided in Table 6.

5.19.6.5 Overview of National, Institutional, and Legal Framework for Integrated Management

In the countries of the Volta Basin, there are many if not too many institutions in charge of managing water resources. This has sometimes resulted in the overlapping of responsibilities and difficulties in coordination. Coordination of activities among the institutions was found to be generally weak (Obuobie and Barry 2010). An integrated approach at the local and national levels with emphasis on intersectoral coordination has been proposed.

The current legal framework in relation to the effectiveness of the laws governing resources appears to be weak and ineffective (Obuobie and Barry 2010). In many cases, laws are adequate but are not adhered to or enforced. This has mostly been due to lack of institutional capacity or political commitment.

Table 6 Aspects of proposed legislative and regulatory interventions to achieve environmental quality objectives in the Volta Basin

Environmental quality objective	*Targets*	*Activities*	*Interventions*	*Type of intervention*	*Root causes*
Balanced aquatic ecosystem	Achieve adequate surface water quality by 2012	Establish common methods for assessing water and sediment quality including bioassays of coastal biota	Develop guidelines for methods of water, sediment, and biota monitoring and assessment (including sampling, analysis, and risk assessment)	Legislative/ regulatory	Insufficient scientific capacity
			Implement a first periodic assessment (3-year interval) of the river quality and trends	Investment	
			Develop and establish national/regional land-based activities data and information management system as a tool for contaminant assessment and management	Data management	
		Fill gaps in knowledge of priority pollutants (contaminant levels) and major sources of pollutants (contaminant inputs)	Conduct regional assessment of priority land-based activities, sources of contaminants, and pollutant levels in water and sediments	Scientific investigation	Insufficient scientific capacity
			Conduct routine targeted monitoring of riverine sediments and biota for purposes of identifying major hot spots of pollution and land-based activities	Investment	
		Exchange environmental data and information	Develop agreements and technology basis for the free and regular exchange of environmental data and information within the region	Data management	Insufficient scientific capacity; inadequate technical infrastructure
		Reduce impacts of urban areas on water quality	Construct or extend sewage collection systems in all major cities in the basin and route discharges to treatment plant	Investment	
			Upgrade/renovate existing treatment plants for mechanical and biological treatment	Investment	
			Expand solid waste collection in all major cities and improve disposal methods so waste does not runoff or leach into waterways	Investment	

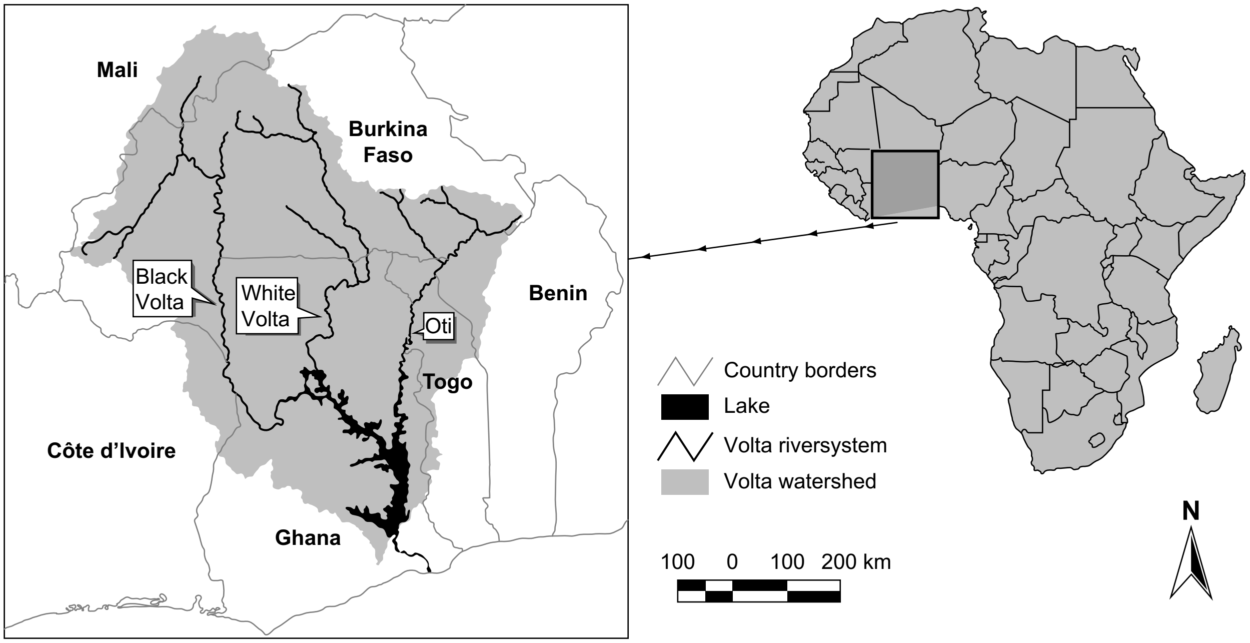

Figure 8 The Volta Basin.

5.19.6.5.1 Regional Coordination

There have been several initiatives at the regional level to manage water resources. For example, the West African Regional Action Plan for Integrated Water Resources Management (WARAP-IWRM) was initiated by the Government of Burkina Faso with the support of Danish International Development Agency (DANIDA). This regional cooperation arrangement that started in 1997 within the Economic Community of West African States (ECOWAS) has proposed the establishment of a regional structure for coordinating and monitoring the West African Regional Initiatives for Integrated Water Resources Management.

Another regional cooperation effort for the integrated management of water resources is being developed by the Global Water Partnership (GWP) and its technical group, the West African Technical Advisory Committee (WATAC), with the aim of preparing regional programs of action to implement the West African water vision for the twenty-first century.

Other initiatives in the region include the GLOWA Volta Project on integrated assessment of feedback mechanism between climate, land use, and hydrology.

In addition to multilateral cooperation, bilateral cooperation also exists among the riparian countries of the Volta for mitigating environmental issues and problems. Such cooperation efforts include the Burkina Faso–Ghana Joint Committee for managing the water resources of the Volta Basin as well as Burkina Faso–Cote d'Ivoire committee for the development of programs for integrated management of water and cooperation in matters of environment and forest, for example.

5.19.7 Social Issues in the Volta Basin

5.19.7.1 Population

The countries of the Volta Basin are among the fastest growing populations in the world. Burkina Faso represents 43% of the total area of the basin, and about 78% of the total population lives in the Volta Basin. In Togo, the Volta Basin covers 48% of the country's land and was home to 35% of the total population in 2000 (Obuobie and Barry 2010). The Volta Basin has an estimated population of approximately 25 million people, growing at a rate of 2.5% year^{-1}. The population of the Volta Basin is estimated to increase by as much as 80% over the next 25 years (Andah 2005) (Figure 8, Table 7).

5.19.7.1.1 Population Distribution

Population density within the countries that make up the Volta Basin vary, with the highest found in Togo (118 km^{-2}), followed by Ghana (86 km^{-2}), and the lowest in Mali (9 km^{-2}) (Table 8). However, there are also intracountry variations in the geographic distribution of population. For example, the population density of Ghana's Upper East Regions is 104 persons per km^2, while that of the Northern Region is only 26 persons per km^2. In Côte d'Ivoire, the population density varies from 8 persons per km^2 in the north to 22 persons per km^2 in the south (Gordon and Amatekpor 1999). The average population density in the Volta Basin of Burkina Faso is

Table 7 Population of Volta Basin

Country	*Basin area (%)*	*Population (%)*
Benin	3.41	2.56
Burkina Faso	42.9	47.6
Cote d'Ivoire	2.48	2.13
Ghana	41.6	35.8
Mali	3.12	3.35
Togo	6.41	8.55

29 inhabitants per km^2, with a high population density (79 inhabitants per km^2) on the Central Plateau and sparsely populated eastern and western regions (10 inhabitants per km^2) (Obuobie and Barry 2010).

5.19.7.1.2 Population Structure

The population of the basin is young. The major portion of the basin population falls into the working age group of 15–64 years. The basin's population is also largely rural (between 56% and 83%). The countries with the lowest percentage of rural population, Côte d'Ivoire and Benin, have over 50% of their people living in the rural areas, whereas Ghana, Mali, and Togo have close to 66% of their people living in rural areas (Obuobie and Barry 2010).

5.19.7.1.3 Migration

Migration in the Volta Basin is influenced by a number of factors such as poverty, increasing population pressure, and environmental degradation. The easy movement of people across national boundaries in the subregion under the ECOWAS protocol makes population pressure a transboundary cause of many of the environmental problems in the basin. For example, the establishment of the Volta Lake upstream in Ghana resulted in a decline in the fishing industry in the Lower Volta, causing people to move upstream to live near the lake for their livelihood. In Togo, some people in the basin (Savannas and Kara regions) who migrated to the southern regions of the country before 1990 are now returning because of sociopolitical unrest (Obuobie and Barry 2010; World Bank 2010). The population of Burkina Faso experiences an important migration at both internal and external levels. It is estimated that of 100 migrants, 71.2% migrate inside the country and 28.8% abroad (Obuobie and Barry 2010).

5.19.7.2 Human Resources

The young-age structure of the Volta Basin presents opportunity in terms of human resources. However, low educational levels as well as poor access to health facilities in many parts of the Volta Basin have affected the quality of human resources available. Hence, social development in the basin's countries remains problematic.

5.19.7.2.1 Education and Literacy

Although many of the basin countries such as Ghana have made important strides toward reaching the Millennium Development Goal of achieving universal primary education, there are still significant disparities in the schooling and literacy rates for males and females within the countries in the basin. For example, primary completion rates are still lower for females (Table 9). Female intake rates are generally lower than male for all countries, except Ghana. Adult literacy rates for males and females are worst for Burkina Faso and Mali, with Benin and Côte d'Ivoire in the middle. Female illiteracy rates are higher than male illiteracy rates

Table 9 Education and literacy levels in the Volta River Basin countries

Country	Gross primary enrollment ratio	Net primary enrollment ratio	Adjusted net enrollment ratio, primary		Primary completion rate	Adult literacy	
			Male 2008	Female		Male	Female
Benin	117	93	99	86	65	54	28
Burkina	79b	63b	68b	60b	38	37	22
	74	–	–	–	48	64	44
Ghana	102	74	74	75	79	72	59
Mali	91	72	81	68	57	35	18
Togo	105	83	91	80	61	77	54

Source: World Bank, 2010: *World Development Indicators*, World Bank, Washington, DC.

for all countries in the Volta Basin (Asante 2006). These disparities are the bases of existing gender issues related to differential access to resources, distribution, and processing, where women currently play a significant role, yet are often marginalized.

5.19.7.2.2 Health

In Ghana there have been serious health issues associated with the Volta Lake, in particular the two major diseases schistomiasis (or bilharziasis) and onchocerciasis (or river blindness). The dam virtually halted the rate of flow in the Volta River, increasing stagnant water conditions and, consequently, creating ideal breeding grounds for carriers of waterborne diseases. Before the construction of the Akosombo and Kpong dams, malaria (from mosquitoes) was not much of a problem along the swift-flowing Volta River, but after it became a stagnant lake, malaria became a greater public health concern in lakeside villages. Likewise, only 1–5% of the population suffered from schistosomiasis (a disease transmitted by snails) before the dam was constructed (Obuobie and Barry 2010). Before the creation of the Volta Lake, infection rates of schistosomiasis in the area had been 1–5%. The problem of Bilharzia in the lake basin must be seen as a disease, which embraces both the lake and the Volta Delta. The migratory habits of the fishermen ensure the spread of the disease from endemic to other areas. The construction of the second dam at Kpong also eliminated the breeding sites downstream of Akosombo and therefore stopped the transmission of the disease in the vicinity. Despite the increases in health facilities across the countries, infectious diseases are still the main cause of death among poor people.

5.19.7.3 Living Standards

The gross domestic product (GDP) is the sum of value added by all resident producers plus any product taxes (less subsidies) not included in the valuation of output. Growth is calculated from constant price GDP data in local currency (Asante 2006). The Volta River Basin countries, except Ghana and Togo, are considered to have low human development and possess underdeveloped economies (Table 10). They are described as being among the poorest nations in the world, with an average per capita GDP of about US\$ 1500 year^{-1}. Mali, Burkina Faso, Benin, and Ghana have more than 70% of their population living below the US\$2 a day poverty line. Four main causes of poverty have been identified in the Ghana part of the Volta Basin (Asante 2007; Nick Van De Giesen et al. 2001):

- Type of available economic activities (fishing, agriculture)
- Degree of water insecurity (poor access, health impacts, loss of labor)
- Environmental impact of upstream catchment activities (dams, farming practices)
- Water-related diseases (malaria, guinea worm, etc.)

Table 10 Macroeconomic indicators in the Volta River Basin countries

Country	GDP per capita 2006 (US$)	2007/2008 human development index	Population living below US\$1 day^{-1} (%)
Benin	536	163	31
Burkina Faso	416	176	27
Côte d'Ivoire	952	166	15
Ghana	532	135	45
Mali	498	173	36
Togo	356	152	Not available
Average	550	–	31

GDP, gross domestic product.
Source: Gao, Y., and A. Margolies, 2009: Transboundary water governance in the Volta River Basin.

5.19.7.3.1 Access to Potable Water

Access to safe drinking water varies from 50 to 84%. In general, access to safe drinking water is lower in rural areas than in urban areas. The majority of the population lives in rural areas, with agriculture being the most important occupation. The number of rural households having access to safe water from boreholes, pumps, or piped water taps is only 53%, compared to 83.3% in the urban area. Among the most extreme rural poor only 51% have access to safe water, while among the least poor, 73% have safe water.

5.19.7.4 Income and Employment

About half the population in each of the riparian countries is in the age group of 15–64 years, which forms the majority of the labor force. This age pattern theoretically means that the basin is significantly rich in human resources. Among the six basin countries, Ghana has the largest labor force (9.5 million), followed by Côte d'Ivoire (6.6 million), Burkina Faso (5.7 million), Mali (5.4 million), Benin (2.9 million), and Togo (1.9 million). In the Ghanaian part of the Volta Basin, 80% of the population is rural and 20% urban.

The basin countries are largely rural (64–88 %), and the people depend, to a large extent, on the exploitation of natural resources for their livelihood. The agriculture sector employs the largest share of the labor force (60–92%) (Obuobie and Barry 2010). Economic development depends on agriculture because no alternatives exist in other sectors. Staple crops are sorghum, millet, and corn grown under rain-fed conditions. Average yield lies between 800 and 1000 kg of grain per hectare. Irrigation is generally seen as necessary to control the risks in order to achieve sustained higher levels of production (Benneh 1973). The high population density on the central plateau, which lies entirely within the Volta Basin, and the high levels of intensive farming (between 50 and 70%) mean that the agrodemographic threshold has been reached, if not exceeded, and has led to a process of land degradation. Agriculture generally employs more women than men. For example, in Côte d'Ivoire, agriculture accounts for 54% of male employment but 72% of female employment (Obuobie and Barry 2010).

The services sector is next to agriculture (6–30%), with industry ranking third (2–16%). The services sector is dominant in the urban areas, whereas agriculture dominates in the rural areas. Burkina Faso has only minor mining and industrial sectors.

5.19.8 Major Farming Systems and Land Tenure in the Volta Basin

5.19.8.1 Bush Fallow

The bush fallow system of farming is widely practised in all the agroecological zones of the Volta Basin. Under this farming system, the family or household is the unit of decision making and production, and there is heavy reliance on personal and family labor for farming activities. The farming system is characterized by the use of simple tools and fire for clearing vegetation, and there is heavy dependence on the inherent fertility of the soil (Hunter 1969). The use of fire is a means of conserving energy, and the ash from burning makes some minerals (phosphates and potash) readily available for use by plants. Crops grown are basic food staples including cassava, yam, cocoyam, plantain, maize, and vegetables. Farm sizes are usually small, and the cropping system adopted is mixed, which help provide the subsistence needs of the family. Land ownership is communal, and the right to cultivate a piece of land is a birthright and/or with the consent of the land-owning group (Hunter 1969).

The bush fallowing practice involves cultivation of parcels of land on a rotational basis, because a piece of land gets exhausted after two or three successive periods of cultivation. In the forest agroecological zone in particular, there is close relationship between the soil and vegetation in terms of nutrient exchange. Clearing of the vegetation breaks this normal cycle, and the soil loses its nutrients through leaching. The farmer is therefore compelled to abandon the deficient land for it to restore its fertility through the natural nutrient exchange cycle. Thus, there is rotation of fields instead of crops (Hunter 1969). The length of the fallow period varies from place to place depending on prevailing local ecological and sociocultural factors. Essentially, there should be plenty of cultivable land in relation to the population of the land-owning group so that pieces of land could be allowed sufficient time to regain their fertility through the natural system. However, increasing pressure on land in most districts has led to shortening of fallow periods from between 6 and 10 years to between 2 and 3 years (Hunter 1969). Consequently, most lands are not able to regain their fertility, leading to poor crop yields.

Benneh (1973) identified two types of bush fallow systems, the mosaic pattern of land use and the strip pattern of land ownership. The latter is associated with the huza system of the Krobos. It originated when groups of people organized themselves to purchase lands, which were distributed on the basis of individuals' capital contribution. The distribution was done from a common baseline, giving rise to the strip pattern. The group, however, became a coherent social unit with a leader and team of elders responsible for ensuring peace among members and settling potential boundary disputes.

The bush fallow system remains the dominant mode of producing major food crops in the country, for which the forest–savannah transitional zone is noted. Increase in land area under cultivation constitutes the dominant mode of increasing agricultural production. This trend has left a legacy of widespread devegetation/deforestation, which threatens the very basis of this farming system. Also, as the number of members of the land-owning group increases, the land becomes progressively fragmented, farm sizes are drastically reduced, and fallow periods are shortened. Indeed, trends in population growth, increasing demands on the agricultural industry, increased recognition of the value of land, and changes in societal organization as a whole are gradually transforming the bush fallowing system of farming. The fundamental challenge is how to utilize lands effectively to achieve the desired levels of food production to feed the increasing population against the backdrop of land cover transformation and climatic change. Not surprisingly therefore, farmers are increasingly adopting the use of agrochemicals (fertilizers and pesticides), tractors, and other farming techniques to achieve higher crop yield.

5.19.8.2 Permanent Systems

Permanent field cultivation has been associated with traditional cash crop production in the forest region. The crops involved are cocoa, oil palm, rubber, and kola for the market (Hunter 1969). In recent times, however, and particularly in the forest–savannah transitional zone, cashew and mango have become very important tree crops. The nutrient status of the soil under this farming system is largely assured through decomposition of dead vegetation from the crops on the land. The produce is sold for cash. Tree crops may be interplanted with food crops in the initial stages of the farm when the tree canopies are not well formed. Cocoa trees are necessarily interplanted with food crops such as plantain and bananas.

Farm sizes are relatively bigger, and there is the use of hired labor. The right of use of land for cash crop farming is usually guaranteed for fairly longer periods through outright purchase or long leasehold. Share-cropping arrangements also exist between land owners and tenants. Individuals belonging to land-owning groups negotiate with members of their respective groups for putting lands under permanent field cultivation. Benneh (1973) has indicated that a member of the land-holding group who grows cash tree crops has greater control over his piece of land, which strengthens the individual's interests in the land. This could be understood as one of the ways in which the traditional land tenure system is being transformed.

5.19.8.3 Compound Farming

Compound farming is undertaken in the savannah agroecological zone of northern Ghana. It involves permanent utilization of land immediately surrounding a homestead for crop cultivation, hence the name compound farming. Household refuse and animal droppings are used to improve the fertility of the soil, ensuring sustainable crop cultivation. However, the intensity of use of manure diminishes radially outward from the housing structures (Tonah 2001). Crops grown are also varied and include leguminous leafy vegetables, groundnuts, and beans, as well as early maturing varieties of guinea corn and maize, which the household depends on while working on distant farms under the bush fallow system. The stalks of harvested guinea corn and maize may be used as fuel. Members of the compound unit consisting of the man, his wives, children, and unmarried brothers and sisters constitute the production and consumption unit. Simple tools including the hoe and the dibble stick are employed for sowing and managing crops on the land.

The layout and pattern of land holdings reflect family structure and stages in community evolution (Tonah 2001). Traditionally, the compound may have several dwellings for members of the whole unit, a granary and a cattle yard. The settlement pattern is dispersed, with each compound having its home farmland. The settlement pattern and agricultural practice are therefore closely interrelated (Tonah 2001). Therefore, the shift from dispersed settlements toward nucleated settlement pattern or concentration of compounds will radically transform the compound farming system. Nucleated settlements have the advantage of planning for the provision of social amenities such as schools, potable water, and clinics.

5.19.8.4 Mixed Farming

Mixed farming is an agronomic practice that integrates elements of both livestock keeping and crop cultivation. The practice is systematic, involving controlled grazing and utilization of animal droppings to improve soil fertility for crop production. The animals are confined and/or controlled when the crops are growing. Once the crops are harvested they are allowed to feed on the stubbles of the grains and remains of other crops. In the process, they spread their droppings on the soils, which in turn improves soil fertility.

Mixed farming was introduced to densely populated northeastern Ghana in the 1930s by the colonial government to check soil deterioration and to increase agricultural productivity (Hunter 1969). Apart from the use of compost from cow dung, animal traction and planting on ridges were also introduced. Production of cow dung for compost was intensified and promoted through stall-feeding of work animals (zero grazing). Farmers also use compost of household refuse and kitchen sweepings and the sweepings from sheep and goat pens.

The development of mixed farming is in response to increased population pressure on land and the need to use land more efficiently to obtain the greatest possible returns. It holds tremendous potential for maintaining the integrity of the environment for increased food production.

5.19.8.5 Livestock Production

Much of the Volta Basin lies within the savannah agro-ecological zone, which is noted for livestock production as in other savannah lands in tropical Africa. Cattle are of great commercial significance. Households also raise goats, sheep, pigs, chicken, and guinea fowl, which are sold to support family income. Women own small ruminants and poultry of various kinds, but cattle are largely the preserve of men. The region is the main supplier of livestock to urban centers in the southern part of the country. The animals are usually transported live in trucks.

The principal cattle breed is the West African Shorthorn, which is hardy and well adapted to the environment. The cattle (and small ruminants) are allowed to roam freely in the dry season and feed on the remains of harvested crops but are confined and restricted during the wet season. The zebu herds have been introduced from neighboring countries by the Fulani, who trek to seek pasture and water. In recent decades there has been increasing number of Fulani pastoralists in the Volta Basin, particularly along the shores of the Volta Lake. The migrant Fulani pastoralists are able to establish reciprocal relationships with the local host populations. They usually reside at the outskirts of villages, keeping their own cattle and those of the indigenous population and other migrants, as well as of urban-based cattle owners (Appawu et al. 2006). The activities of the pastoralists have led to many cases of conflict with crop growers and local people.

5.19.8.6 Interface between Land Evaluation and Farming Systems

The broader issues of use of land for other activities, increasing population, environmental change, and economic and socio-cultural dynamics of society have implications for farming systems. Farmers respond to changes in environmental conditions, land-holding arrangements, technological innovations, market forces, and government policies. For example, high population densities in northeastern Ghana led to the introduction of mixed farming during the 1930s (Hunter 1969), which incorporated elements of the traditional compound farming system. In response to land shortage, farmers in these areas migrate to seek new agricultural lands in less populated areas in the forest–savannah transitional zone of the middle belt of the country.

In the country as a whole, there is growing recognition of the value of land as a major source of wealth. As a result, trustees of land and influential community members engage in outright sale of land and thereby deny other family members the right of use of land. There are also cases of litigation over ill-defined land boundaries, which sometimes lead to communal conflict. These developments together with increasing population have led to progressive fragmentation of agricultural lands and reduction in farm sizes and fallow periods. In the periurban areas, agricultural lands are lost to estate development as the incentives for the sale of lands appear more attractive to land owners. However, in view of growing demand for food in the urban centers, open space in urban and peri-urban areas are utilized for intensive cultivation of mainly vegetables. Such initiatives have become part of the urban land-use structure and hold prospects for promoting urban employment and reducing urban poverty.

Increased environmental pressures such as extraction of wood for fuel will continue to transform farming systems. The forest–savannah transitional zone is the major source of charcoal for urban markets in the southern part of the country. Wood fuel is also an important energy source for a majority of households in the Volta Basin. Continuous wood harvesting, land clearing for new farms, and incessant bush fires have led to reduction in tree stock and drastically reduced the vegetation cover in many areas.

Pressure on land and the need to produce cash crops for sale has gradually brought about innovative farming techniques. There is increasing use of agrochemicals among farmers as they strive to increase crop yield against the backdrop modifications in ecosystems, changes in climatic conditions, and transformations in social arrangements. Drawdown farming along the Volta Lake and flood recession farming in the channels of shallow rivers in the dry season are practiced by farmers in the riparian areas. A number of irrigation schemes such as Tono and

Vea have been in operation since the late 1970s, but there are tremendous opportunities to harness more of the larger rivers for irrigation using appropriate water-lifting technologies.

5.19.9 Health and Environmental Changes in the Volta Basin

5.19.9.1 Prevailing Water-Related Diseases: Pre- and Postimpoundment Era

The prevailing water-related diseases in the Volta Basin, pre-impounment of the river at Akosombo, were yellow fever, malaria, trypanosomiasis (African sleeping sickness), urinary schistosomiasis (bilharzia), and onchoceriasis (river blindness) (World Bank 2010). Although malaria and schistosomiasis were prevalent, they were not much of a problem along the swift-flowing Volta River (Obuobie and Barry 2010). Only 1–5% of the population suffered from schistosomiasis (a disease transmitted by fresh water planorbid snails) before the dam was constructed (Obuobie and Barry 2010).

Yellow fever and dengue were the most important arthropod-transmitted viral infections in the early part of the resettlement period in the lake area (World Bank 2010). The mosquitoes that transmit these infections (*Aedes aegypti*) were found to breed mainly in small collections of water in tins, earthen jars, coconut shells, etc. These health problems were, however, given much attention because of their high fatality rate and subsequently controlled. It may be presumed that yellow fever and dengue have reduced public health significance, and, hence, not much has been reported in recent literature on the infection status of these diseases in the Volta Basin post dam era. Nevertheless, Appawu et al. (2006), in their study on entomological assessment of the risk of transmission of hemorrhagic fever in the Northern Region of Ghana, observed that the main contributory factor to the high larval indices of the vectors was the unavailability of pipe-borne water, which invariably leads to storage of water in pots and barrels for long periods, especially during the dry seasons, in households, which allows for the breeding of *Aedes* sp. The possibility of reimmergence of these conditions are worth investigating, as effects of climatic change with its attendant water shortage will result in storage of water in containers for longer periods, which will provide the appropriate breeding sites for these mosquitoes.

Onchocerciasis, the parasitic disease causing river blindness was very prevalent in the preimpoundment era. Although literature on the prevalence of the disease is limited (Obuobie and Barry 2010), there is circumstantial evidence of a drastic reduction in the disease mainly as a result of change in the water ecology from the fast flowing riverine system, which provided a suitable environment for the vector *Simulium damnosum*, to a slow flowing system after the dam, which was not suitable for vector development. In addition, the 20-year Onchocerciasis Eradication Programme, which started in March 1974, achieved much success. The discovery of Ivermectin for mass treatment also significantly impacted on the prevalence of onchocerciasis in the Volta Basin.

While onchoceriasis reduced with the construction of the dam, schistosomiasis or bilharzia increased in prevalence. The change in the river system to a slow flowing river with the bloom in aquatic vegetation such as *Ceratophylum* sp. supported the proliferation of the snail vector that transmitted the *Schistosoma* parasite. Prevalence in school children was 5% according to an epidemiological survey made in 1960–61 before the lake was formed. By 1979, urinary schistosomiasis had become the most prevalent disease in the area, affecting some 75% of lakeside residents. Today, both the intestinal and, particularly, urinary forms of the disease are prevalent in the Volta Basin of Ghana. Intestinal schistosomiasis is common in the estuarine communities below the Akosombo dam, whereas urinary schistosomiasis is widespread in the whole Volta Basin. Recent studies have also found 10.6% of women in the Lower Volta Basin of Ghana to have genital schistosomiasis (Mahama et al. 2005) (Figure 9).

Trypnosomiasis is a disease caused by the parasite *Trypanosoma*, which affects humans and animals. Among humans it is known to cause the disease known as sleeping sickness. Human trypanosomiasis was prevalent along the Volta River as the forests, preimpoundment era, provided a habitat for the vector *Glossina* sp. (testse fly). The formation of the lake was,

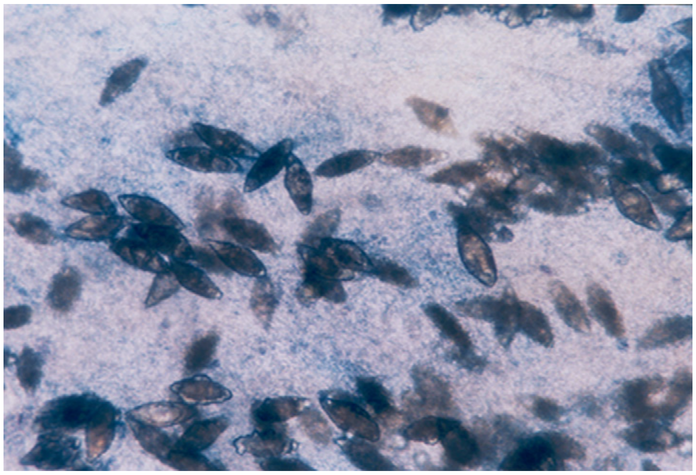

Figure 9 *Schistosoma haematobium* ova in cervical tissue. Source: Yirenya-Tawiah.

however, beneficial in the control of this disease as it drowned the large area of forest that habored the tsetsefly (World Bank 2010). Since 1973, no new cases have been recorded around the lake.

Bovine trypansomiasis, however, continues to be endemic in the northern portion of the Volta Basin in Ghana. A longitudinal study conducted along the White Volta and its tributaries showed the predominance of *Trypanosoma vivax* in tsetseflies captured from their study area (Osório et al. 2008). The effects of bovine typanosomiasis include loss in beef, milk, and leather production (Smithsonian Report 1974).

5.19.9.2 Environmental Changes in the Volta Basin

5.19.9.2.1 Aquatic Weeds

Preliminary studies conducted preimpoundment of the Volta River indicated many aquatic weeds to be present in the basin, but well-known aggressive forms, e.g., papyrus (*Cyperus papyrus*), water hyacinth (*Eichhornia crasippes*), kariba weeds (*Salvinia molesta*), and alligator weed (*Alternanthera philoxeroides*), were absent (Akrasi 2005). The main riverbed was infiltrated with very few aquatic weeds resulting from annual floods, with most of the aquatic weeds found in the riverine lagoons and other tributaries (Akrasi 2005).

Soon after the damming of the river, the change in ecology began to support the proliferation of aquatic weeds. These include *Pistia*, *Vossia* spp., and *Ceratophyllum*. This created suitable habitats for fish, whereas the ceratophyllum's submerged beds house large populations of *Bulinus* snails that habor the *Schistosoma* parasites. In recent times, there has been the invasion of water hyacinth in the Volta Lake and Lower Volta River channel right down to the estuary. This, coupled with the effects of climatic change, provides a big threat to the reduction of the basin size because of its aggressive nature of spread (**Figure 10**).

5.19.9.2.2 Sediment Changes

Sedimentation is recognized as a potential problem in Volta Lake, both in terms of loss of water storage capacity and role of sediment-associated nutrients and contaminants in degrading its water quality and aquatic ecosystems. However, assessment of potential sediment problems is hindered by limited information on the magnitude of the suspended sediment fluxes entering the lake from its numerous tributaries and the overall sediment input to the lake basin. The Volta River Engineering Report indicated from preimpoundment studies that the capacity of the reservoir was such that "no measurable reduction due to siltation could take place in the lake for several hundreds of years" (Akrasi 2005). Before the construction of the Akosombo dam, the highest measurements of suspended sediment concentration of the Volta River at Ajena in 1956, at the height of the flood season, did not exceed 90 mg l^{-1} near the surface (Akrasi 2005).

Akrasi (2005) indicated that the suspended sediment concentrations observed were relatively insensitive to an increase in the discharge. In the case of the Afram River at Aframso, the exponent of the sediment load discharge relationship is <1.0, indicating that the concentrations tend to decrease when the discharges increase. The exponent values according to Akrasi (2005) are substantially lower than the typical values between 2.0 and 3.0, as cited by Gregory and Walling (1973). These low exponent values suggest that the rivers remain turbid over a wide range of flows, and the suspended sediment concentrations remain relatively high during low flows. This situation could also reflect the relatively low gradient of the river system and the importance of localized storms in generating local sediment inputs to the river system, which are essentially unrelated to the overall water discharge regime. Overall, Akrasi (2005) estimated the mean annual suspended sediment input into Lake Volta to be $\approx 17 \times 10^6$ t year^{-1}, which is equivalent to a mean annual specific suspended sediment yield of 52 t km^{-2} year^{-1}.

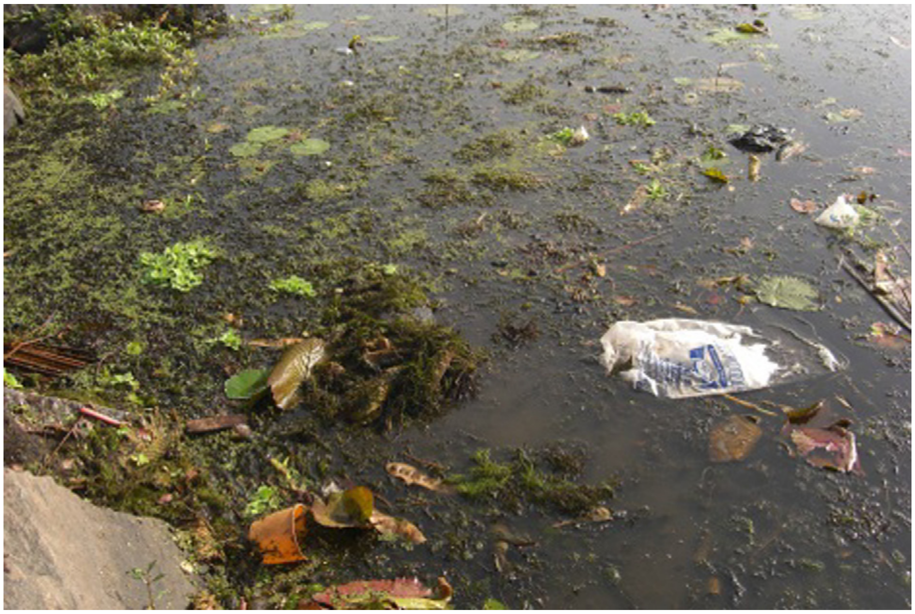

Figure 10 Proliferation of the Kpong Headpond with *Ceratophyllum damnosum*. Photograph by Dzidzo Yirenya-Tawiah.

Although the observed sedimentation rates are still low, continuous monitoring of sedimentation is necessary, as there is intensive erosion leading to siltation and sedimentation of the river channel due to deforestation as a result of activities of people living in uncontrolled human settlements.

5.19.9.2.3 Channel Morphology (Sandbars)

Some morphological changes have occurred along the stretch of the Volta River, particularly downstream of the river at Akuse and in its delta zone. Since 1974, the point at which the Volta entered the sea is known to have shifted 12 km eastwards in a channel, which runs parallel to the coast (Obuobie and Barry 2010). This phenomenon of gradual eastward shift of the mouth of the Volta River has been known in the past, but the process seems to have been accelerated since the construction of the Akosombo dam and the flood flushing of the river mouth stopped. Subsequently, the changes that have occurred in the delta zone with its potential disastrous effect on estuarine communities from any rapid floods have prompted the VRA to artificially reestablish a direct flow into the sea through dredging. Channel morphological changes are also probably linked to accelerated coastal erosion at Ada. Before dam construction, seasonal floods flushed out sandbars, which might have started during the dry season; thus, the estuary was largely kept free of sandbars. However, after the construction of the dam, because of the absence of annual floods, sandbars gradually formed at the estuary and in time virtually blocked inflows from the river to the sea (Figure 11).

5.19.9.2.4 Deforestation

The Volta River Basin in Ghana is one of the areas experiencing rapid deforestation in West Africa. The vegetation in the basin is characterized by SDF, savanna, and woodland types (Gregory and Walling 1973). Predictions show that about 20 and 25% of all sub-basins within the Black Volta and Daka sub-basins, respectively, would experience deforestation as a result of an increase in population (Kumi 1973). In the Lower Volta Basin, the Afram plains and other areas in the south have been the focus of increasing settlement and agricultural development since the 1960s. The forest and transitional areas are intensively farmed with cocoa, coffee, plantain, cocoyam, cassava, oil palm, and maize on small bush fallow plots. A large modern commercial farm at Ejura specializes in maize production. Some timber extraction also takes place in these areas, and the area serves as a major source of fuel wood for charcoal making.

The VRA has taken serious measures to avoid eventual silting of the lake. The authority has sponsored two afforestation projects intended to stop erosion around the lake. In the Adjena Gorge, VRA and the Forestry Department have declared the steep areas bordering the lake as protected lands. VRA also funded another pilot afforestation project in the low slope areas around Yeji in the Brong Ahafo region. The objective of this project is to encourage fishermen to plant wood lots and adopt the use of improved stoves, which use less fuel wood for fish smoking. It is hoped that this project would help to restore some 580 ha of tree cover and reduce the dependency on fuel wood by 60 % in the Yeji area.

5.19.9.2.5 Seismicity

Historically, most parts of Ghana are seismically stable but for the triangle extending southeastward from the Togo quartzite, or roughly from a line joining the cities of Accra and Ho. Initial assessment of lake seismicity revealed that the creation of the lake would add extra weight to the underlying rocks to the tune of 165 million metric tons when the lake reaches its estimated capacity of 165 km^3. The significance of this on seismic activity was, however, not known since the necessary seismic measurements were not made during the filling of the lake.

In November 1964, when about 28 km^3 of water had been impounded, an earthquake of intensity of five on the modified Mercalli scale occurred with its epicenter located near Koforidua, about 40 km south of the reservoir. In December 1966, another earthquake occurred when the total impoundment stood at 102 km^3, and a third occurred in February 1969

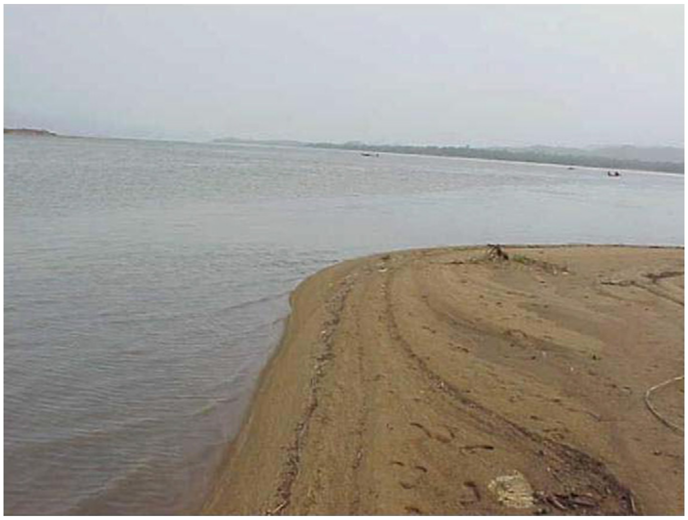

Figure 11 Sandbar on the Volta River mouth.

with storage at 162 km^3, but the epicenters for these shocks were offshore from Accra and more remote from the lake (Obuobie and Barry 2010). These incidents led Kumi (1973) to conclude that at least the 1964 incident, which had its epicenter within 40 km of the reservoir, could be attributed to crustal readjustments associated with the initial stages of the lake's infilling. Earthquake-triggering effects include change in pressure, change in weight, and vibrations.

5.19.9.2.6 Microclimatic Changes

Expected significant microclimatic changes due to transformation of bare or vegetated land into a water body was predicted during Volta Lake formation. In addition, it was also anticipated that the creation of the Volta Lake would increase atmospheric moisture by making more water available for evaporation. Oral accounts of sudden changes in wind speed on the Volta Lake and surrounding areas have been documented by Moxon (1984). Similar reports of observed changes in local weather conditions were corroborated by the residents during field survey of the impact of water projects in Ghana by the personnel of Water Resources Research Institute (De-Heer Amissah 1969). On the other hand, a study on the impact of the Volta Lake on the local climate in Tamale and Kete Krachi in the north and Akuse and Accra in the south, 2 years after the filling of the lake, by De-Heer Amissah (1969) found no significant changes in the monthly rainfall amounts at the four stations, even though a tendency toward decreasing rainfall amounts at Kete Krachi and increasing amounts at Tamale was becoming evident. The mean monthly maximum temperature since 1964 at Kete Krachi seemed to be lower than the pre-project 10-year mean, whereas the minimum temperatures were higher than the 10-year mean. Work by Opoku-Ankomah (1996) on the rainfall pattern of Accra from 1935 to 1995 divided into decades, i.e., 1936–45, 1946–55, etc., showed that there was a gradual rise of total rainfall from the beginning of 1936–45 to the 1956–65 decade and a decline thereafter till 1986–95.

5.19.10 Conclusion

The Volta River Basin is one of the largest river systems in West Africa, and the water resources of the basin are important for consumptive use, i.e., domestic and industrial water supply, crop irrigation and livestock watering, as well as for nonconsumptive use, which includes hydropower generation, fisheries, recreation, and tourism. The status of communities within the Volta Basin is affected by the type of economic activity available (mainly agriculture and fisheries), the degree of water insecurity (which affects access to safe drinking water and water-related diseases), as well as environmental impacts of upstream activities. High population growth rates and associated impacts of reduced land cover and deforestation, coupled with global climatic change, are affecting the ecological condition of the Volta River Basin. Increased agricultural production systems have led to the degradation and overexploitation of terrestrial and aquatic natural resources. There has also been an increase in the number of large and small dams as a consequence of rising numbers in settlements in Ghana, Benin, and Burkina Faso. The construction of these dams has caused contamination, reduced water storage capacity, and loss of aquatic ecosystems as a result of increased sedimentation, invasive aquatic species, increased proliferation of aquatic weeds, and downstream changes to the delta zone that affect estuarine processes and cause coastal erosion.

With the rising trend of prolonged dry seasons and flooding events due to excessive rainfall, the basin is experiencing a growing scarcity in water resources. A number of climate models and the comparisons of various scenarios with different assumptions have projected a decrease in rainfall of 25–30% (Jung 2006), an overall slight increase in total yearly rainfall with strong spatial and temporal heterogeneity (Kasei 2009; Kunstmann and Jung 2005), or reduced flows during the dry season and increased flows in the rainy season (Laube et al. 2008). Other studies have reported a 17% increase in surface runoff resulting in higher discharge (Kasei 2009) or 29% increase in subsurface flow leading to 33% increase in discharge (Obuobie 2008) by 2039. However, it is important to recognize that, at best, these model predictions only include a subset of possible temperature and precipitation conditions in the coming decades (Pielke et al. 2012).

Nevertheless, to reduce risk, there should be the development of a more resilient system, if there is an overall increase in seasonal river flow variability in the Volta Basin (Paeth et al. 2005; Pielke et al. 2011). With increases in the frequencies of extreme drought and flood events, there would be impacts on agriculture and food security in addition to further deterioration in water quality, reduced hydropower generation, and spread of water-borne diseases such as malaria, onchocerciasis, and schistosomiasis/bilharzia. Future actions to manage the Volta Basin should incorporate population growth and development demand on resources by all countries within the Volta Basin. With the uncertainties in long-term changes in climate statistics and short-term variability, focus should be placed on improving the ability to manage future possibilities by reducing the current vulnerability of the society and communities to climatic variability and extreme events, improving and updating management options to deal with the worst-case scenarios and taking advantage of possible opportunities. Implementation of various adaptation measures, such as water conservation, reduction in water demand and use, new strategies for drought- and flood-resistant farming, and the application of appropriate and pragmatic management practices, will all contribute to the reduction in the impacts of climate on water resources.

Within the Volta Basin, a number of institutions are responsible for managing water and soil resources, which has resulted in the overlapping of responsibilities and poor coordination. In order for the management of water and soil resources to be effective, it should be integrated at the local and national level, with emphasis on intersectoral coordination. Management strategies in place are also not effectively enforced as the governance of the basin is currently afflicted by insufficient political support, lack of financial resources, gaps in information, insufficient stakeholder participation, and poor institutional coordination and collaboration. There is the need to address these inherent challenges as well as recognize the advantages and opportunities of effective management of the Volta Basin in sustainable development, adaptation, and energy technologies. Further developments within the basin should not be based on short-term income generation but include long-term sustainability. There is the need for further research to improve the knowledge base for effective integrated management of the transboundary resources in order to optimize activities, including the management of dams, and restore livelihoods and ecosystems both upstream and downstream. Studies and strategies to address anthropogenic impacts and climate on the Volta Basin should incorporate assessment, sustainable use, development, and management of resources in an integrated way.

Glossary

Fossil aquifers Aquifers that were recharged during previous wet climatic periods and are receiving negligible modern recharge.

Paleo-recharge Recharge that occurred during previous wet climatic periods.

Autochthonous recharge Recharge resulting from the infiltration of precipitation over the aquifer outcrops.

5.20.1 Introduction

Many of the arid and hyperarid parts of the world are blessed by having large amounts of potable fresh water stored in large extensive (kilometer-thick) aquifers stretching for hundreds to thousands of kilometers across political boundaries; these are largely nonrenewable aquifers, commonly referred to as 'fossil' aquifers, with little or no modern recharge. They were largely recharged under previous wet climatic periods. These aquifers are extremely important to the general population of these countries given the prevailing arid conditions and the growing need for fresh water supply arising from a general trend of increasing population. The aquifers are vulnerable to pollution, unsustainable overexploitation, and disputes over transnational boundary issues. However, despite their importance to the sustenance of the population of the arid world, the majority of these aquifers remain poorly investigated. Possible causes include their locations in less-developed parts of the world, the general inaccessibility of many of these areas, difficulties in collecting background information, and the unavailability of local funding and expertise to support research in these areas. As a consequence, our current understanding of the fossil groundwater systems in many of the arid and hyperarid parts of the world is lacking in many respects. Specifically, the following elements remain poorly constrained: (1) nature and causes of spatial and temporal mass variations and the extent to which these aquifers are being depleted, (2) timing

http://dx.doi.org/10.1016/B978-0-12-384703-4.00531-1

and mechanisms of modern and paleo-recharge, (3) locations and amount of discharge, (4) movements of deeper circulating groundwater in these systems on a regional scale, and (5) the hydraulic connectivity of subbasins within the aquifer. We address these important issues in one of the largest fossil groundwater systems in the world, the Nubian Aquifer System of northeast Africa. We apply an integrated approach for data collection, analysis, and distribution that addresses the difficulties cited above and leads to the development of realistic conceptual and groundwater flow models and sustainable management scenarios for these aquifers. Such models are urgently needed to protect the precious groundwater resources from pollution, overexploitation, and disputes over water rights near international boundaries. In addition, the models should assess the predictability of the hydrologic effects associated with climate variability and longer term change.

5.20.2 Geologic and Hydrologic Setting of the Nubian Aquifer System

Beneath the surface of the hyperarid Western Desert of Egypt and adjacent portions of eastern Libya, northeastern Chad, and northwestern Sudan (Figure 1) lies an immense reservoir (150 000 km^3) of fresh groundwater in the Nubian Aquifer System (Thorweihe and Heinl 2002). This precious resource is largely a fossil groundwater reservoir with minor recharge compared to the discharge. It contains the equivalent of more than 500 years of Nile River discharge (Thorweihe and Heinl 2002). The Nubian Aquifer System has two major basins: (1) the Kufra Basin of Libya, northeastern Chad, and northwestern Sudan, and (2) the Dakhla Basin of Egypt (Figure 1). Water in the Kufra basin flows from the south to north and in the Dakhla Basin from the south-southwest to north-northeast (average gradient $\sim 0.5\,\mathrm{m\,km^{-1}}$) and naturally discharges at oases (Thorweihe and Heinl 2002).

The area of the Nubian Aquifer System is about 2 000 000 km^2. The aquifer mainly consists of continental sandstones with intercalated shales of shallow marine and deltaic origin of the pre-Upper Cretaceous age, unconformably overlying Proterozoic basement. The aquifer reaches a thickness approaching 4000 m in the deepest parts of the basin (Thorweihe and Heinl 2002). The sandstone is exposed in northeast Chad, southeast Libya, northern Sudan, and southwest Egypt. North of the 25th parallel in Egypt, the Nubian Aquifer is confined beneath thick marine shales of the Upper Cretaceous age. North of the 29th parallel, northward groundwater flow is limited by saline water. Where the aquifer is confined, it is divided into four thick (tens to hundreds of meters thick) horizons of sandstone layers that are separated by relatively thin (meters to tens of meters thick) shale layers. These horizons are commonly referred to as zones A, B, C, and D, where A is the shallowest and D is the deepest. Despite the large variations in thickness of each of these zones, they are readily correlated over extensive areas in the Western Desert of Egypt from electric and radioactivity well-logging records (Thorweihe 1982).

Water in the Nubian Aquifer naturally discharges in oasis areas. Since large-scale extraction began in the 1960s, water levels have substantially decreased in these areas, especially in western Egypt and Libya. Water quality throughout the Nubian Aquifer is generally good, and it is viable as a drinking-water source and for irrigation with little or no pretreatment. Particular concerns regarding the protection of the aquifer's water quality are related to domestic and industrial wastewater treatment and solid waste management practices in water extraction zones. The level of natural radioactivity in the Nubian Aquifer water has not yet been well characterized, but studies of equivalent water in Jordan have shown high levels of radium (Vengosh et al. 2009).

5.20.3 Origin and Evolution of the Nubian Aquifer System

Two models have been proposed to explain the origin of the waters of the Nubian Aquifer: (1) large-scale flow from mountainous recharge areas in Chad (Ball 1927, Sanford 1935), and (2) autochthonous recharge during more humid climatic conditions that previously prevailed throughout the present desert area (Sultan et al. 1997, Thorweihe 1982). The former hypothesis is supported by the regional gradient in groundwater surface in Egypt, Libya, Chad, and Sudan; highest in the southwest and lowest in the northeast. The latter model is partly supported by the stable isotopic and age data for the Nubian groundwater in the Western Desert of Egypt that range from thousands to hundreds of thousands of years (Sturchio et al. 2004, Patterson et al. 2005).

There are several problems with both models. The large-scale flow model (hypothesis 1) is inconsistent with recent findings (Sturchio et al. 2004, Patterson et al. 2005) that show a progression of groundwater ages (^{81}Kr, ^{36}Cl) within the Dakhla basin from southwest (East Uweinat: <30 kyr) to northeast (Bauti-1: 1000 kyr), which suggest that autochthonous recharge of deep groundwater in Egypt primarily occurred at the foothills of the Uweinat mountain range (Gebel Uweinat) and not in Chad (Ennedi Plateau), as previously advocated by the large-scale flow models (Figures 1 and 2). We show that the autochthonous recharge within the Dakhla basin is further corroborated by the apparent presence of major paleodrainage networks in the extensive Nubian Sandstone outcrops, the network extending from the foothills of the Uweinat mountains toward the River Nile. Although the observed paleodrainage patterns could have resulted from massive groundwater discharge during previous wet climatic periods, a more likely interpretation is that they represent paleo-recharge areas. The relatively young ages of the groundwater in the postulated recharge areas support the latter interpretation (Froehlich et al. 2007). Simply put, it would take much more than 30 kyr (the age of groundwater in East Uweinat) for the groundwater to travel from Chad to the vicinity of east Uweinat.

The autochthonous recharge concept (hypothesis 2) is inconsistent with the reported (Ball 1927) hydraulic gradient (from southwest to northeast) and the expected flow given the large transmissivity of the Nubian Sandstone. With more and more wells being drilled across the Nubian Aquifer, it is becoming clear that the original distribution of head data was oversimplified given the paucity of well data at the time and that recharge is probably occurring at the foothills of the highlands in Chad and in other areas as well (e.g., Gebel

Uweinat). Figure 2 is an initial potentiometric map of the Nubian Aquifer System that we generated from initial head data extracted from wells (yellow dots in Figure 2) in Egypt, Sudan, Libya, and Chad (CEDARE 2001).

Both models assume that the Nubian Aquifer was entirely recharged in previous wet climatic periods and are thus at odds with meteorological data and with inferences made from radiocarbon and stable isotopic data which indicate that the Nubian Aquifer is being locally recharged by modern water in some areas. Considerable precipitation ($>150\,\mathrm{mm\,yr^{-1}}$) (Legates and Wilmott 1997, Nicholson 1997) occurs over the recharge areas where the Nubian Aquifer crops out in central Sudan and in northeast Chad. Published isotopic and geochronologic data indicate that in northern Sudan and in southwest Egypt (areas closer to the recharge domains), radiocarbon ages for Nubian Aquifer waters are relatively young and that oxygen and hydrogen isotopic compositions are enriched compared to those of groundwater to the north (Hesse et al. 1987; Thorweihe 1990; Froehlich et al. 2007), possibly indicating mixing between fossil groundwater and modern precipitation in recharge areas to the south. Using the Sinai Peninsula as a test site and adopting integrated methodologies, we have shown that the Nubian Aquifer is receiving modern recharge in areas of relatively high precipitation (Sultan et al. 2011).

As previously described, there are four stratigraphic zones within the Nubian Aquifer in the Western Desert of Egypt that are believed to be hydraulically interconnected over large segments of the Western Desert (Brinkmann et al. 1987). This understanding might not be the case where uplifts (e.g., Uweinat-Aswan, Uweinat-Howar, **Figure 1**) could restrict flow from one part of the aquifer to another. Geochronologic and isotopic data show that the Uweinat-Aswan uplift restricts groundwater flow and we emphasize the importance of understanding the role of these uplifts across the aquifer as an important step toward the development of sound conceptual models and the construction of realistic groundwater flow models. To the best of our knowledge, the existing Nubian Aquifer models (e.g., Brinkmann et al. 1987; Euroconsult-Pacer 1983; Soliman et al. 1998) treat the aquifer as being hydraulically interconnected across its entire spatial extent. Newer data indicate the complexity of the Nubian Aquifer System and show the need for the re-evaluation of the existing models for the origin and evolution of the Nubian Aquifer groundwater.

5.20.4 Temporal and Spatial Mass Variations across the Nubian Aquifer Using GRACE Data

To date, there are no reliable estimates for the temporal and spatial variations in discharge (natural and manmade) and recharge across the Nubian Aquifer, nor is there an adequate understanding of the connectivity of the various subbasins within the Nubian Aquifer. This is largely due to the large areal extent of the aquifer and the paucity of field data on a regional scale, a situation that is hindering the development of sustainable management schemes for this valuable resource. We address this problem by first examining temporal and spatial mass variations across the investigated areas extracted from satellite temporal gravity measurements from GRACE to identify areas within the aquifer that are showing signs of declining water supplies. Then we propose various solutions that can allow for sustainable utilization of this valuable resource.

5.20.4.1 Processing of GRACE Data

The GRACE satellite mission was launched in March 2002 to map the temporal variations in the Earth's global gravity field on a monthly basis (Tapley et al. 2004). Variations in the Earth's gravity field are caused by changes in the Earth's mass distribution. Almost all of the variability that occurs on the relatively short time scales accessible with GRACE (i.e., seasonal to interannual) is due to mass variations at or near the Earth's surface. Generally, the largest time-variable gravity signals observable in GRACE data come from changes in the distribution of water and snow stored on land (Wahr et al. 1998).

Because GRACE provides measurements that average over large areas, it is well suited for examining hydrologic processes in the Nubian Aquifer, one of the world's largest aquifers in both areal distribution and storage capacity. The hydrologic setting of the Nubian Aquifer provides opportunities to investigate a wide range of hydrologic issues of worldwide relevance, including the magnitude of recharge, discharge, and the role the uplifts might play as barriers to groundwater flow. Discharge is primarily concentrated in the northern areas in Libya, and in Egypt this occurs both in natural depressions and in areas where major water extraction projects are underway, whereas recharge and infiltration are primarily concentrated in the southern portions of the aquifer area where most precipitation occurs. The provenance in the distribution of the recharge and discharge areas in the Nubian Aquifer alleviates complexities that might be encountered in studying similar systems in temperate areas with concurrent recharge and discharge, which could render the interpretation of GRACE data more difficult.

We used the University of Texas Center for Space Research Release-4 (UT-CSR RL04) GRACE gravity field solutions that span the period from April 2002 through November 2010 (101 months). The UT-CSR RL04 gravity field solutions were processed using procedures described in Ahmed et al. 2011. The temporal mean was removed, a destriping filter was applied, destriped solutions were smoothed using a Gaussian function (250 km radius), and the results were converted into surface mass values (in units of equivalent water thickness) on a 0.5×0.5 degree grid. To obtain results for an individual discharge area (see below), we averaged together the results for every grid point lying within that area. All GRACE-derived mass fields were interpreted as reflecting changes in water storage, given: (1) the slow rates of the mass variations in the underlying solid Earth, (2) an absence of large earthquakes and glacial isostatic adjustment in the region, (3) the small to negligible contributions related to mass fluctuations from the adjacent ocean (Wahr et al. 1998) and the corrections applied to remove the time-variable oceanic gravity signal from raw GRACE measurements (Tapley et al. 2004), and (4) the fact that errors in the atmospheric pressure corrections applied to GRACE data are likely to be negligible in this region (Velicogna et al. 2001).

5.20.4.2 Seasonal and Annual Trends in Libya, Egypt, Sudan, and Chad

Time-series analyses for the GRACE monthly gravity solutions show seasonal patterns and interannual trends (**Figure. 3**). Positive interannual trends are interpreted here to indicate increasing water storage probably due to enhanced recharge, and negative trends indicate decreasing water storage probably due to excessive water extraction and natural discharge. Changing volumes of water impounded in artificial lakes behind dams can also give rise to positive or negative interannual trends on local scales.

Examination of the GRACE time series over discharge areas in the Nubian Aquifer in Egypt and eastern Libya shows a seasonal cycle with highs in the months of June to August and lows in the months of December to February (**Figures 3(a) and 3(b)**). We suspect that these patterns are largely

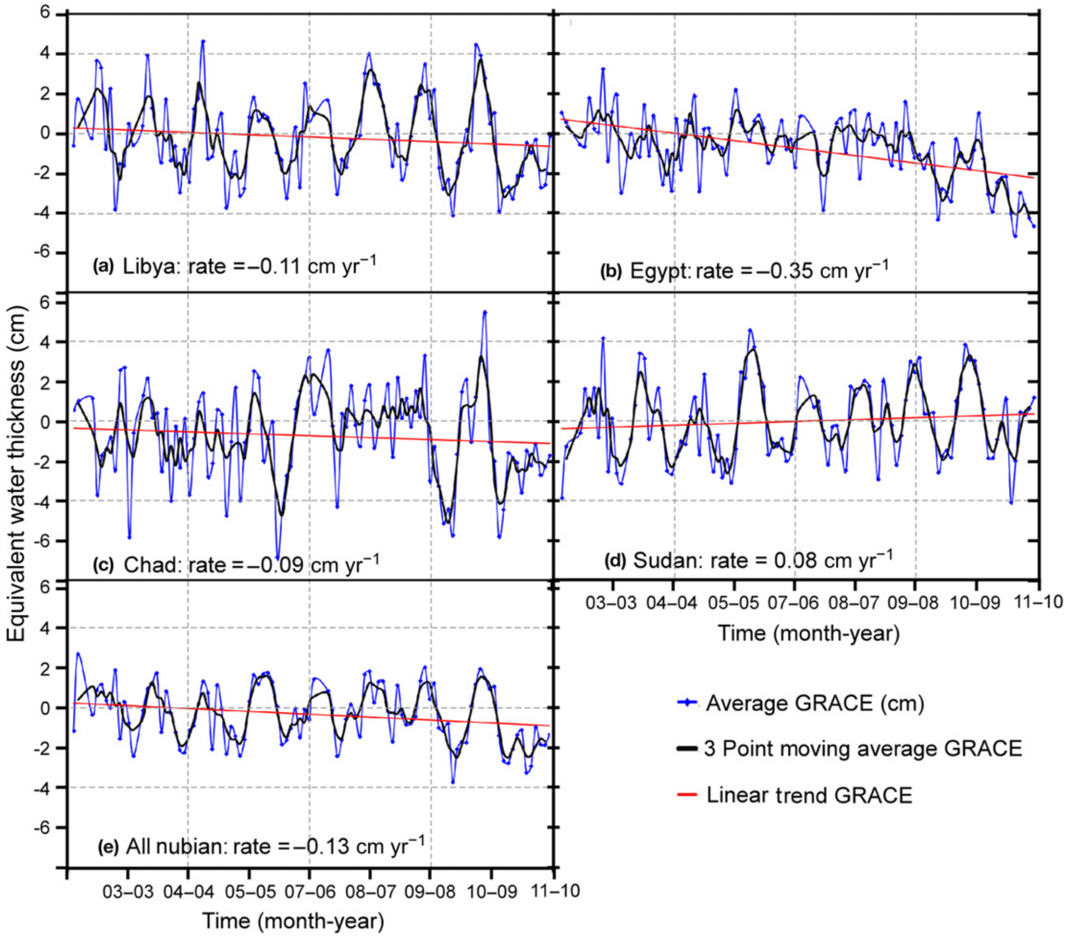

Figure 3 Time-series analysis for the GRACE monthly gravity solutions showing seasonal patterns, and/or interannual trends for areas of discharge in Libya (a) and Egypt (b), as well as recharge in Chad (c), Sudan (d), and the entire Nubian Aquifer (e). Also shown are the best fit linear trend line for each of these data sets; regression trend lines are significant at 99% and 95% levels of confidence for Egypt (b) and for the entire area of the Nubian Aquifer (e), respectively. Linear trends for areas cited as showing steady to near-steady conditions are significant at lower levels of confidence (level of confidence: Libya 80%; Sudan 71%; Chad 63%).

related to the uneven patterns of extraction throughout the year. Because most of the water extracted from the Nubian Aquifer is used for agricultural purposes that largely occur throughout the winter season, the maximum losses in mass are observed during this time period. In the summer, the extracted water is replenished to a large extent by inflow of groundwater. If this is true, the average annual extraction could be estimated from the observed temporal trends in the product of the area of the Nubian Aquifer and difference between the water thickness in the summer and winter seasons averaged over the investigated period. We also observe an interannual progressive depletion amounting to $-2.35 \times 10^9\,\mathrm{m}^3\,\mathrm{yr}^{-1}$ ($-3.5\,\mathrm{mm\,yr}^{-1}$) in Egypt, and $-0.39 \times 10^9\,\mathrm{m}^3\,\mathrm{yr}^{-1}$ ($-1.1\,\mathrm{mm\,yr}^{-1}$) in Libya. It is noteworthy that the overall decline over the entire Nubian Aquifer System ($-2.65 \times 10^9\,\mathrm{m}^3\,\mathrm{yr}^{-1}$; $-1.3\,\mathrm{mm\,yr}^{-1}$) could be largely accounted for by the mass depletions over Egypt. These depletions are probably related to a progressive increase in extraction rates with time in these areas that exceed replenishment by groundwater flow from neighboring locations. Progressive water extraction programs were initiated in the 1960s to use the Nubian Aquifer water for irrigation and drinking purposes in Egypt and in Libya (Salem et al. 2002). Extraction from aquifers other than the Nubian Aquifer is negligible; the Nubian Aquifer is the most extensive in area and dimension of all aquifers in Egypt and in Libya, and is by far the most heavily used of all the aquifers (AbuZeid and AbdelMeguid 2006) in these two countries.

The GRACE time series over recharge areas in Chad and Sudan show a seasonal cycle with highs in the months of August and October and lows in the months of May to June, lagging a month or two behind peak precipitation in the area. These seasonal patterns of precipitation and GRACE were accounted for by (Ahmed et al. 2011). They claimed that with the onset of the precipitation period over the recharge areas, a fraction of the water is captured through initial losses, increasing soil moisture, and creating local ponds and sinks; and, thus, increasing the accumulated water and mass. With continued precipitation and mass accumulation, the GRACE results continue to rise; they peak at a point where the soil moisture content approaches saturation. With the decline of precipitation, mass accumulation gradually diminishes to the point at which water received in the soil profile from precipitation is less than that lost to evapo-transpiration and to outflows (runoff, overland flow, interflow, and groundwater flow). This marks a halt to additional increases in water thicknesses and the onset of the effects of mass deficiency. As the rainy season comes to an end, precipitation tapers off and factors such as evaporation, transpiration, and runoff progressively decrease accumulated water, reducing the GRACE response until it bottoms out.

Inspection of Figure 3 shows negligible to small interannual variations in mass with time in Chad ($-0.12 \times 10^9\,\mathrm{m}^3\,\mathrm{yr}^{-1}$; $-0.9\,\mathrm{mm\,yr}^{-1}$) and in Sudan ($0.69 \times 10^9\,\mathrm{m}^3\,\mathrm{yr}^{-1}$; $0.8\,\mathrm{mm\,yr}^{-1}$). We interpret these patterns to indicate steady-state to near-steady-state systems where there are subequal amounts of infiltrating water and water leaving the recharge areas through evapo-transpiration, runoff, and overland and groundwater flow toward the discharge areas in the north. Similar steady-state to near-steady-state conditions are observed over Libya; there, natural and artificial discharge is apparently compensated for by groundwater that can readily flow unobstructed from recharge areas to the south. One explanation for the observed interannual progressive depletion in Egypt is that the east-west trending Uweinat-Aswan uplift is impeding groundwater flow from recharge areas in the south. In the next sections, we attempt to explain the observed mass variations described above by examining modern and paleo-recharge regimes, locations and magnitudes of discharge, and connectivity of subbasins.

5.20.5 Connectivity of Subbasins

A prominent basement uplift within the Dakhla catchment, the Uweinat-Aswan uplift could be traced on the surface by a series of basement outcrops that trend in an east–west direction (Figure 1). The presence of this uplift that is largely formed of basement rocks suggests that the Nubian Aquifer to the north of the uplift is partially disconnected from the Nubian Aquifer to the south of the uplift. This implies that areas to the north of the uplift will experience greater effects of the extraction of groundwater from the Western Desert Oases (Kharga, Dakhla, Farafra, and Baharya).

This suggestion is corroborated by the progressive decrease in ages from the northeast to the southwest within the Dakhla basin and by the observed differences in isotopic compositions of groundwater to the north and south of the uplift. The oldest ^{81}Kr age ($\sim$1 million yr) was obtained from Bauti-1 and the youngest ^{36}Cl age (<30 kyr) from East Uweinat (Figure 4) (Sturchio et al. 2004, Patterson et al. 2005). Additional support for this hypothesis comes from comparing the isotopic compositions of groundwater samples north and south of the uplift; samples north of the uplift are isotopically depleted compared to samples south of the uplift. The average isotopic composition for 37 samples to the north of, and proximal (<250 km) to, the Uweinat-Aswan uplift is δ^{18}O: $-10.7‰ \pm 0.9‰$ (Figure 5, solid red dots), whereas that for seven samples to the south of and proximal to the uplift is δ^{18}O: $-8.6‰ \pm 1.4‰$ (Figure 5, solid green dots). Simulations have also shown that the discharge of Lake Nasser into the Nubian Aquifer is impeded by the Aswan Uplift (Kim and Sultan 2002). They concluded that, in their study area, the basement surface forms an impervious lower boundary for the aquifer and acts as a barrier to lateral groundwater flow.

We suggest that GRACE data could potentially be used to gain further insights in the connectivity of subbasins within the Nubian Aquifer that are separated by basement uplifts. If these are restricting groundwater flow, one could expect to observe differences in the seasonal and annual variations across them. Alternatively, there would be no differences if the subbasins are hydraulically well-connected. One measure of the annual and seasonal variations is a standard deviation (SD) image extracted from monthly GRACE solutions (Figure 5). For example, if the east-west trending Uweinat-Aswan uplift is restricting the groundwater flow from the south to the north, one should observe differences in the standard deviation image across the postulated barrier (Figure 5). Examination of GRACE data on either side of the Uweinat-Aswan uplift shows that indeed this is the case (Figures 3(b) and 3(d)), uplift could be impeding groundwater flow from the south.

Throughout the areas occupied by the Nubian Aquifer in neighboring countries there are several other uplifts that could restrict and/or redirect groundwater flow. Examples include the north–south trending Uweinat-Howar uplift in northern Sudan. Because of its north–south trending orientation, this uplift is not restricting the flow of groundwater from the south to the north as is apparently the case with the Uweinat-Aswan uplift. Unfortunately, it is difficult to evaluate the effect of the Uweinat-Howar uplift on groundwater flow because of the absence of reliable residence times, isotopic and geochemical data, and/or groundwater levels and flow directions for the surrounding areas.

5.20.6 Patterns of Paleo-Recharge

Samples of Nubian Aquifer groundwater from wells in the Dakhla basin in the Western Desert of Egypt were measured for ^{81}Kr, ^{36}Cl, and other chemical and isotopic constituents (Figure 4). The range of ages thus derived is <30 kyr–1000 kyr (Sturchio et al. 2004; Patterson et al. 2005). Ages increase from southwest to northeast. This age progression supports flow vectors predicted by numerical hydrodynamic models (Brinkmann et al. 1987), verifying lateral flow of deep groundwater toward the northeast, with recharge of deep groundwater occurring southwest of Dakhla and not in the distant Chad as previously advocated (Figures 1 and 2). ^{81}Kr ages progressively increase with distance to the north and east of Dakhla; their spatial distribution indicates relatively high flow velocities ($\sim 2\,\mathrm{m\,yr}^{-1}$) from the recharge area toward Dakhla and Farafra, and lower velocities ($\sim 0.2\,\mathrm{m\,yr}^{-1}$) from Dakhla toward Kharga and Baris and from Farafra to Bahariya. These observations are consistent with the areal distribution of hydraulically conductive sandstone within the Nubian Aquifer. Southwestward extrapolation of the $\sim 2\,\mathrm{m\,yr}^{-1}$ flow rate inferred from the difference in ages for Dakhla and Farafra is consistent with recharge primarily in the area of the Uweinat uplift near the Egypt–Sudan border, and is inconsistent with models that advocate recharge over mountainous areas farther south in Chad and its surroundings.

Figure 4 Locations sampled for ^{81}Kr, ^{36}Cl, and other isotopic measurements. Solid circles represent deep (>200 m) wells; hollow circles represent shallower samples. Red numbers are estimated 81-Kr ages in units of 10^3 yr (from Sultan et al. 2007), except for the age of east Uweinat 4, which is a 36-Cl age estimate (from RIGW, 1993). Also shown are the saline-/freshwater interface (orange line) and outlines of the Nubian Aquifer (thick black line) and river Nile (light blue line). Modified from Patterson, L. J., N. C. Sturchio, B. M. Kennedy, et al. 2005: Cosmogenic, radiogenic, and stable isotopic constraints on groundwater residence time in the Nubian Aquifer, Western Desert of Egypt. *Geochem. Geophys. Geosyst.*, **6**.

We inferred the existence of paleo-recharge areas in the Uweinat uplift area and its surroundings. Paleodrainage channels in Nubian Sandstone bedrock were identified using space-borne radar data that are capable of penetrating the sand sheets (Figure 6(a)). We show that the distribution of drainage networks extracted from satellite-derived digital topography also reflect to a large degree the distribution of underlying paleodrainage systems (now partly buried under sand sheets). Thus, the present topographic drainage networks could be readily used to facilitate mapping the overall distribution of buried paleodrainage networks in areas where radar data are missing. The underlying assumption is that the sand sheet blanket does not obliterate, but rather reflects, the underlying topographic variations. The correspondence between the channel network visible in radar data and that derived from digital topography supports this suggestion.

We defined the drainage channels in the area of the Selima Sand Sheet in Southwestern Egypt using SRTM and ARC/INFO (full-featured geographic information system) watershed delineation routines (ESRI 1991)(Figure 6(b)). The SRTM dataset is a space shuttle-based radar interferometric data set, which provides improved topographic definition in many parts of the world where only low resolution regional scale data previously existed (Farr and Kobrick 2000; Rabus et al. 2003).

directly recharged (shaded pale blue) are shown in Figure 6(a). Some well locations depicted in Figure 5 are also shown for reference. Figure 6(a) shows a drainage pattern that extends from southwest to northeast. Within the catchment area, there are two major closed drainage basins (Dakhla, Kharga). In these areas there are thick playa deposits that probably mark the locations of paleolakes that developed in these depressions.

These SRTM-based streams were compared to stream distribution inferred from coregistered SIR-C data (Figure 6(b)). Note the clear correspondence between the SRTM-derived channels and the SIR-C derived channels. Space-borne radar data have been previously used to reveal the distribution of buried drainage channels in the Saharan deserts (Maxwell and Haynes 2001; McCauley et al. 1998; McCauley et al. 1982;

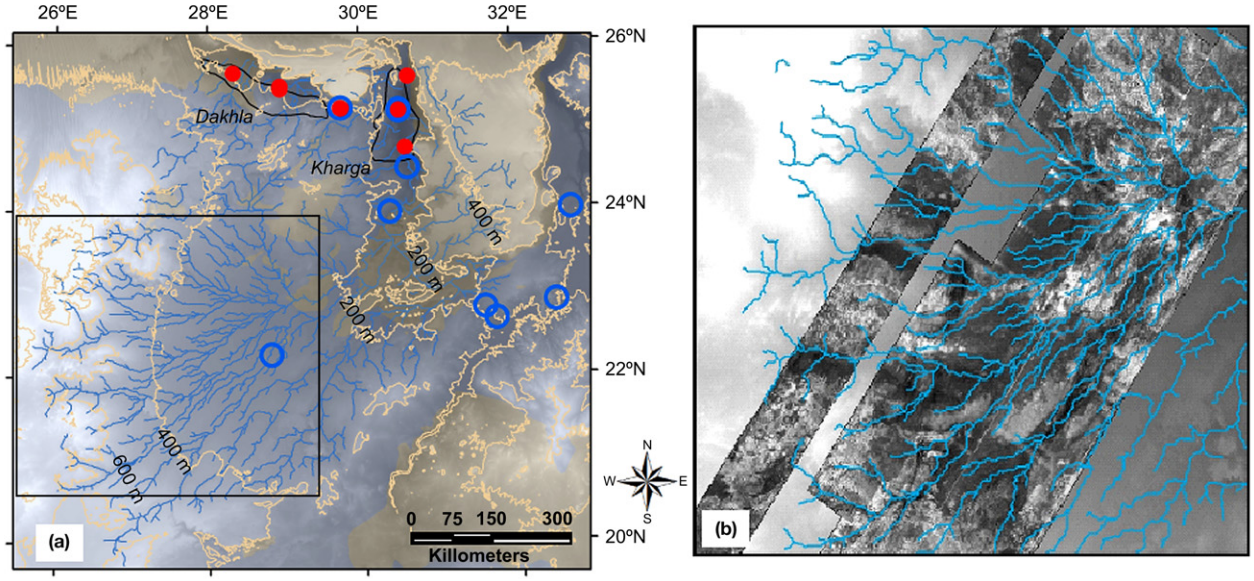

Figure 6 (a) Paleochannels (blue line) in Dakhla basin, derived from SRTM 30 Arc second data. (b) SRTM-derived channels (blue line) overlain onto SIR-C image for the area covered by the box in (a). Also shown are digital elevation contours and groundwater sample locations from Figure 4.

Robinson et al. 2000; Schaber et al. 1997; Stern and Abdelsalam 1996) and to reveal the subtle tectonic fabrics in this area (Abdelsalam et al. 1995; Koopmans and El Fawsti 1996). The buried channels are identified from the differences in SIR-C backscatter between the channels and their surroundings. This difference in backscatter has been attributed to one or more factors (Schaber et al. 1997); (1) concentration of secondary deposits (e.g., iron oxide, calcite, gypsum, halite) with high dielectric permittivity in the channels, (2) abundance of clays that attenuate radar signals, and (3) differences in microroughness between the buried channels and their surroundings.

Using regional SRTM data sets and applying the procedures described above, we mapped the regional extent of drainage networks across the entire areal extent of the Nubian Aquifer and its surroundings (Figure 7). The large sand dune fields in northern Egypt posed a problem for mapping the buried channels, as some dunes are tens of meters high. There, the extracted networks do not reflect the distribution of buried channels, but rather the distribution of elongated lowland fields that separate dunes in these areas. We developed procedures to modify the SRTM data over these areas in ways that strip away the dune fields. Using Landsat Thematic Mapper (TM) images, we first identify all bedrock outcrop locations within the dune fields, then extract the elevation of the individual bedrock locations from SRTM data, and finally generate a modified digital elevation map for the dune field using the generated bedrock elevation data set and applying standard interpolation techniques.

The stream network distribution shown in Figure 7 was generated from SRTM data treated as described above. The displayed stream network distribution covers the following types of channels: (1) active channels that flow year-round (e.g., River Nile Basin channels), (2) ephemeral channels that flow only after a precipitation event (e.g., Eastern Desert and Sinai Peninsula), and (3) buried channels that carried water in previous wet climatic periods but no longer presently flow. Most of the mapped streams are underlain by Nubian Aquifer outcrops, and thus through transmission losses they could have contributed to the recharge of the Nubian Aquifer along their length throughout the previous wet climatic periods.

5.20.7 Patterns of Modern Natural Recharge

We conducted an integrated study (Sultan et al. 2011) using geophysical, geochemical, field and remote sensing data sets, GIS technologies, and continuous rainfall–runoff modeling to examine the validity of a widely accepted notion that the Nubian Aquifer was exclusively recharged by fossil water in previous wet climatic periods in the Quaternary Period. While this statement is largely true for many of the areas occupied by the Nubian Aquifer outcrops, it is not true in areas that receive relatively high modern precipitation. One of these areas is the Sinai Peninsula. In dry climatic periods such as those of today, the precipitation over the mountains in Sinai is channeled downstream over the Nubian outcrops at the foothills of the basement mountainous areas in southern Sinai, providing opportunities for groundwater recharge. In Sinai, we advocated that the Nubian groundwater is a mixture of fossil water and modern precipitation, a model that is supported by interpretations of our geophysical (conventional electrical resistivity) investigations and geochemical data. The interpretation of our geophysical data was found to be consistent with the presence of unconfined Nubian saturated aquifers flooring recharge areas at the foothills of the crystalline basement in the Baraga and Zalaga areas (Figure 8). The isotopic compositions (O, H) for our groundwater samples from wells tapping the Nubian Aquifer underlying recharge areas could be accounted for as mixtures of two endmembers: fossil groundwater with isotopic compositions similar to that of the Western Desert Nubian Aquifer and modern meteoric precipitation, with the latter end member being the dominant component. This

interpretation is supported by the observed increase in modern precipitation from west to east that could explain the progressive west to east enrichment in the isotopic composition of the Nubian Aquifer groundwater. Sinai receives the highest amount of precipitation and its groundwater samples are the most enriched; the Western Desert receives the least amount of precipitation and its samples are the most depleted, while the Eastern Desert receives intermediate amounts of precipitation and the isotopic compositions of its samples are also intermediate.

5.20.7.1 Modeling Modern Recharge of the Nubian Aquifer in Sinai

Conservative estimates for the modern contributions to the Nubian Aquifer in southern Sinai were obtained using

Figure 8 False color Landsat TM image bands 2-4-7 for southern Sinai showing the 20 watersheds (red outline) encompassing Nubian sandstone outcrops (yellow outline) that were modeled using SWAT continuous rainfall–runoff models. The Baraga and Zalaga areas are outlined by the blue and green boxes, respectively. Modified from Sultan, M., S. Metwally, A. Milewski, et al. 2011: Modern recharge to the Nubian Aquifer, Sinai Peninsula: geochemical, geophysical, and modeling constraints. *J. Hydrol.*, **403**, 14–24.

continuous rainfall–runoff models for the watersheds that crosscut the Nubian Sandstone outcrops and act as potential recharge domains for the Nubian Aquifer.

A hydrologic model for the Sinai Peninsula was constructed within the Soil Water Assessment Tool (SWAT) framework to simulate the hydrologic processes using its physically based formulations. Initial losses and direct overland flows in the Hydrologic Response Units (HRUs) were estimated using the US Department of Agriculture's Soil Conservation Service method (SCS 1972), a method that was successfully applied to similar ephemeral watersheds elsewhere (Gheith and Sultan 2002). The physical properties of the HRUs were largely extracted from databases that we generated throughout our previous studies (Gheith et al. 2001; Gheith and Sultan 2002; Milewski et al. 2009). The soil types were extracted from the 1:500 000 geologic map series (Klitzsch et al. 1987a, 1987b) and the land-use maps were derived from the US Geological Survey 1-km global land use and land cover database (Anderson et al. 1976). Evaporation on bare soils and transpiration on vegetated canopy was calculated using the Penman–Monteith method (Monteith 1981). A simplified top soil profile was used in the model where soil properties were dependent on assigned land use and soil types.

Channel flows were estimated using the Muskingum routing method (McCarthy 1938). Channel flows were subject to transmission losses (Neitsch et al. 2005) and negligible losses to transpiration or evaporation were assumed because vegetation is scarce or absent, flows are short-lived, and alluvial deposits flooring the valleys have high hydraulic conductivities. Simulations were performed at daily time steps, using cumulative 3-hourly TRMM (Tropical Rainfall Measuring Mission) data over periods of 24 h and applying monthly average values for temperature, wind speed, relative humidity, and solar radiation as daily estimates.

The adopted model parameters were extracted from our investigations in the Wadi Girafi watershed (Figure 8; area:

3656 km^2), a watershed that collects precipitation from the highlands of central Sinai (Milewski et al. 2009). Wadi Girafi was selected because, in Sinai, the stream flow data needed for calibration purposes are only available at the outlet (Bottleneck station) of this watershed. Moreover, there are similarities in physical catchment descriptors of Wadi Girafi and those of the other investigated watersheds, and thus the key sensitive model parameters (e.g., SCS curve numbers, groundwater water delays) extracted for the Wadi Girafi could be transferred to similar proximal watersheds. The procedures for calibrating (coefficient of determination, R^2: 0.86; coefficient of efficiency: 0.85) the Wadi Girafi watershed were described in detail in Neitsch et al. 2005.

Continuous rainfall–runoff models were simulated from 1998 to 2007 for 20 watersheds in Sinai (Figure 8) using model parameters extracted from the calibrated Wadi Girafi watershed (Milewski et al. 2009). All of the selected watersheds are located at the foothills of the Precambrian mountains and encompass Nubian Aquifer outcrops. The total area of the modeled watersheds in Sinai is 14 209 km^2, whereas the Nubian outcrops covered approximately 8% of the area of these watersheds. Because watersheds to the north that have Nubian Sandstone outcrops are limited in areal extent, they were excluded; thus, our average annual modern recharge estimates for the Nubian Sandstone aquifer in Sinai should be considered conservative estimates.

5.20.7.2 Findings and Implications

The SWAT model results for each of the investigated 20 Sinai watersheds, including the average annual amount of precipitation, initial losses, surface runoff, total watershed transmission losses, and transmission losses over the Nubian outcrops throughout the investigated period, were summarized in Milewski et al. 2009. Nubian Aquifer recharge was assumed to be equal to the estimated transmission losses, consistent with findings from similar arid environments (Bazuhair and Wood 1996; Dettinger 1989; Flint et al. 2000; Milewski et al. 2009).

First-order estimates for Nubian Sandstone recharge for each of the investigated watersheds were obtained by multiplying the watershed transmission losses by the proportion of Nubian Sandstone outcrops in the watershed. The average annual modern recharge for the Nubian Sandstone in Sinai was estimated at $13.0 \times 10^6\,\mathrm{m}^3$ from the sum of annual transmission losses for 20 watersheds for each of the investigated years (1998–2007) averaged by the number of years (10 years).

These findings highlight the importance of modern local recharge of the Nubian Aquifer and bear on its sustainable exploitation in the Sinai and elsewhere where the aquifer is being locally recharged. There are many similar areas that are being recharged by modern precipitation across the Nubian Aquifer. Figure 9 shows estimates of cumulative (2002–09) precipitation over the Nubian Aquifer derived from TRMM 3B42v6 data. Inspection of Figures 1 and 9 shows extensive Nubian Sandstone outcrops south of latitude 29°, and large sectors of these areas, south of latitude 17°, receive substantial precipitation (up 1200 mm yr^{-1}). It is in these areas that the Nubian Aquifer is receiving modern recharge.

5.20.8 Modern Recharge Due to Manmade Structures

Modern recharge of the Nubian Aquifer is not restricted to natural recharge in high-precipitation areas. Building dams can enhance local recharge of the Nubian Aquifer from the large water bodies impounded behind dams. Egypt has increased its water storage capacity by constructing the Aswan Dam and the Aswan High Dam. The construction of the latter entailed the development of an extensive reservoir, Lake Nasser, designed to have a maximum water level 183 m above sea level, a total capacity of $1.6 \times 10^{11}\,\mathrm{m}^3$, a total length of 500 km, and an average width of 12 km (Figure 10) (Said 1993). The project raised the surface water behind the High Dam and resulted in recharge of the aquifer, which previously was discharging into the Nile. Because the Lake Nasser reservoir has approached its maximum storage capacity in the past few years, the depressions to the west in the southern Western Desert of Egypt (Figure 10) are currently being used as a natural flood diversion basin to reduce possible downstream damage to the Nile Valley caused by exceptional flooding. These additional artificial lakes are also recharging the aquifer.

5.20.8.1 Modeling the Impacts of the Aswan High Dam on the Nubian Aquifer

We constructed two-dimensional groundwater flow models to investigate the long-term hydrologic impacts of Lake Nasser in southwest Egypt (Kim and Sultan 2002; Yan et al. 2003). To fully capture interactions between the surface and groundwater in the study area, the model domain included the area covered by the entire Lake Nasser in Egypt and Sudan, the Tushka lakes, and their surroundings. The stages and the temporal variations (over the period 1967–2002) in the areal extent of the lakes under investigation were extracted from CORONA satellite images, Landsat TM, and Digital Terrain Elevation Data (DTED) data and from recorded (1967–2000) surface-water levels for Lake Nasser. The Corona satellites were used for photographic surveillance of strategic areas beginning in June 1959 and ending in May 1972. The topography of the area now covered by water in Lake Nasser was estimated from: (1) the areal extent of Lake Nasser in 1967 (CORONA) and 1972 Multi Spectral Scanner, (2) DTED acquired in 1989, and (3) historic lake levels. Our approach involves the development of a groundwater flow model through identification of model boundaries and initial conditions, then calibration of the model over a 30-yr period (1970–2002). Because the study area is mostly unconfined with relatively simple geologic settings (especially near the lake), a two-dimensional unconfined groundwater flow model was found to be adequate for our modeling purposes. A modular three-dimensional finite-difference groundwater flow model (MODFLOW) (McDonald and Harbaugh 1988) was used to develop the model for the Nubian Aquifer in the study area.

Because the basement crops out to the east and southeast, the model boundaries along these domains were considered as no-flow boundaries. Constant head and variable head equal to the Nubian water table level were prescribed along the southwestern and northern boundaries, respectively (Figure 10(a)). The rationale for this type of boundary condition is the almost constant groundwater level over the past two decades along the

(b) Three-dimensional representation of MODIS draped on topography showing proposed scenario (dashed green line) to channel excess Lake Nasser water across the western plateau in high flood years.

Transient flow simulations were required for model calibration over the calibration period from 1970 to 2002. The calibration was carried out by a trial-and-error fit of simulated groundwater heads to measured values. Calibration targets were established for the residual error statistics, and groundwater parameters were modified until the targets were satisfied. Data availability in the study area was generally limited. More wells are currently being drilled as the Tushka Canal project progresses. Luckily, the older wells (drilled from 1965 to 1980), though limited in number, are concentrated along the lake shoreline, where the interaction between the lake and the aquifer is most pronounced, enabling calibration of the model with confidence. Hydraulic conductivity values and yield coefficients of the aquifer materials and vertical hydraulic conductivity of the clay layer were the principal parameters varied during calibration. Because of the rare precipitation (EMA 1996) and negligible pumping activities, largely restricted to pumping tests (Abdel Karim 1992), precipitation and pumping were assumed negligible throughout the calibration. Anisotropy was also assumed to be negligible. Figure 11 shows a comparison between computed and observed head data at the initial reservoir storage stage (1970), peak lake-level years (1980 and 2000), and low lake-level year (1989). The simulated heads from the calibrated model have a good agreement with observed heads throughout the calibration period.

5.20.8.2 Findings and Implications

Transient simulations suggest that the Nubian Aquifer is significantly affected by recharge from Lake Nasser. The total recharge from Lake Nasser to the aquifer for the period

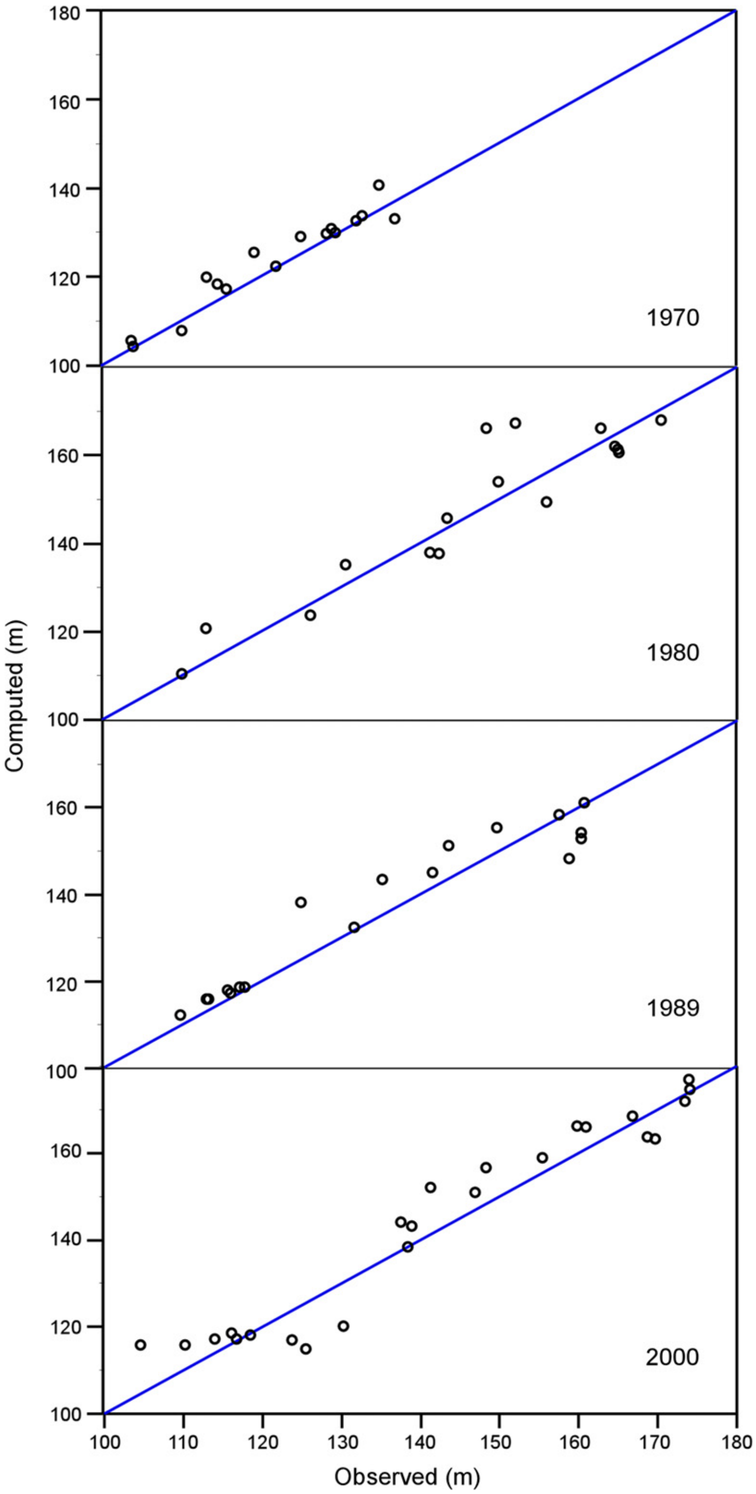

Figure 11 Comparison between computed and observed head data for the years 1970, 1980, 1989, and 2000.

1970–2002 amounts to 10^{11} m^3, which is about 60% of total lake capacity. The peak recharge occurred in the periods between 1975 and 1983, amounting to 6 × 10^{10} m^3, and between 1993 and 2001, amounting to 4 × 10^{10} m^3 (Figure 12). These two periods (1975–83 and 1993–2001) correspond to high lake levels (Figure 12) caused by high inflow to River Nile from the south. Between these two periods, from 1984 to 1987, lake levels dropped below the groundwater table; this resulted in the discharge of groundwater from the aquifer back to the lake. The dynamic change in recharge to the aquifer, as simulated by the calibrated model, indicates a rapidly increasing recharge during the initial

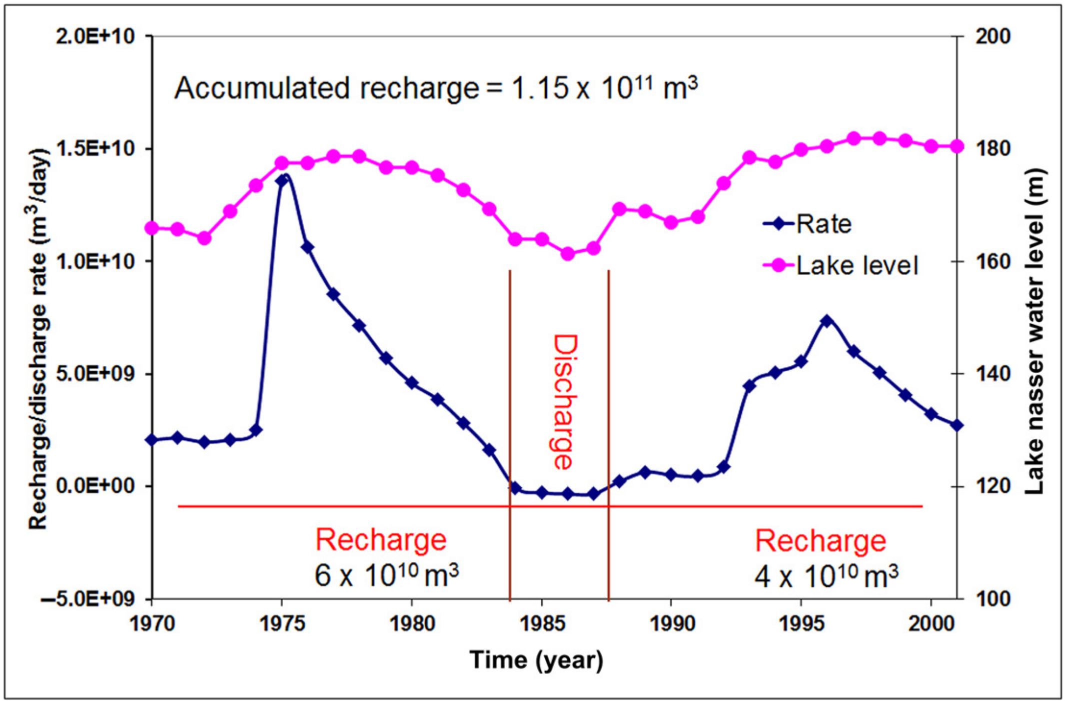

Figure 12 Model outputs: recharge from Lake Nasser to the Nubian Aquifer throughout the calibration period (1970–2002); surface-water levels for Lake Nasser are also shown.

reservoir building period and a gradually decreasing recharge after the lake level and recharge rate peaked. The trend of decreasing recharge is consistent with the gradual reduction of hydraulic gradient between the lake stage and the groundwater level in the Nubian Aquifer. For example, after the lake reached maximum storage capacity, annual recharge decreased by 15–20% each year, from $7.4 \times 10^9\,\mathrm{m}^3\,\mathrm{yr}^{-1}$ in 1996 to $2.7 \times 10^9\,\mathrm{m}^3\,\mathrm{yr}^{-1}$ in 2001.

This progressive decrease in recharge translated into excess water that has been encroaching onto the surrounding depressions. Since 1998, excess water in Lake Nasser has been routed through existing flood diversions to the Tushka lakes and through release of water into the Nile course. The development of the Tushka lakes, changes in lake extent, and lake stages were analyzed using a series of Landsat TM, Moderate Resolution Imaging Spectroradiometer (MODIS), Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), and shuttle images, as well as DTED and ASTER-derived elevation data. The first lake, which emerged in late 1998 on the Tushka depression west of Lake Nasser, covered an area of 400 km^2, with a lake stage 172 m above mean sea level (AMSL). In 2000, excess water from Lake Nasser spread farther west, forming three additional lakes across a lowland area of 750 km^2, with lake stages decreasing from east to west (162 m AMSL at the second lake to 147 m AMSL at the fourth lake). In 2002, the fifth lake developed to the northwest with a lake stage of 144 m AMSL. The five newly developed Tushka lakes cover a total area of 1300 km^2, which is more than 20% of the area of Lake Nasser at maximum capacity (Figure 13).

We developed a surface-water model and calibrated the model by adjusting routing parameters against lake stages identified for 1998–2002. The recharge to the Nubian Aquifer is negligible because most of the Tushka lakes are floored by largely impermeable massive limestone and underlying shales. Simulations indicate that the total volume of water naturally diverted from Lake Nasser to the five Tushka lakes from late 1998 to early 2002 is about $2.74 \times 10^{10}\,\mathrm{m}^3$. Of the diverted water, 61% is stored in the five Tushka lakes and 39% is lost to direct evaporation. If the lake level remains at a maximum, the simulated prediction based on the calibrated model suggests that lakes will continue to develop to the northwest, toward the lowlands west of the plateau, where the permeable Nubian sandstone crops out. Further development of new lakes could potentially generate significant recharge of fresh water to fossil groundwater in the underlying Nubian Aquifer and provide opportunities for sustainable agriculture for the first time in these areas.

5.20.9 Location and Magnitude of Modern Discharge

Many of the areas of natural discharge within the Nubian Aquifer have gone undetected. The discharge has been long recognized as flowing springs within depressions (e.g., Kharga, Dakhla) and along the coastal plain of Gulf of Suez (Sturchio et al. 1996). Using isotopic and geochemical analyses along with field and remote sensing data, we have shown (Sultan et al. 2007) that discharge of the Nubian Aquifer in Wadi Asyuti, an area proximal to the River Nile valley (Figure 1), and in Egypt at large is occurring along the fault complex that defines the River Nile and the Gulf of Suez, where ascending groundwater accesses deep-seated fault systems and discharges into relatively thick alluvial aquifers proximal to these two fault complexes.

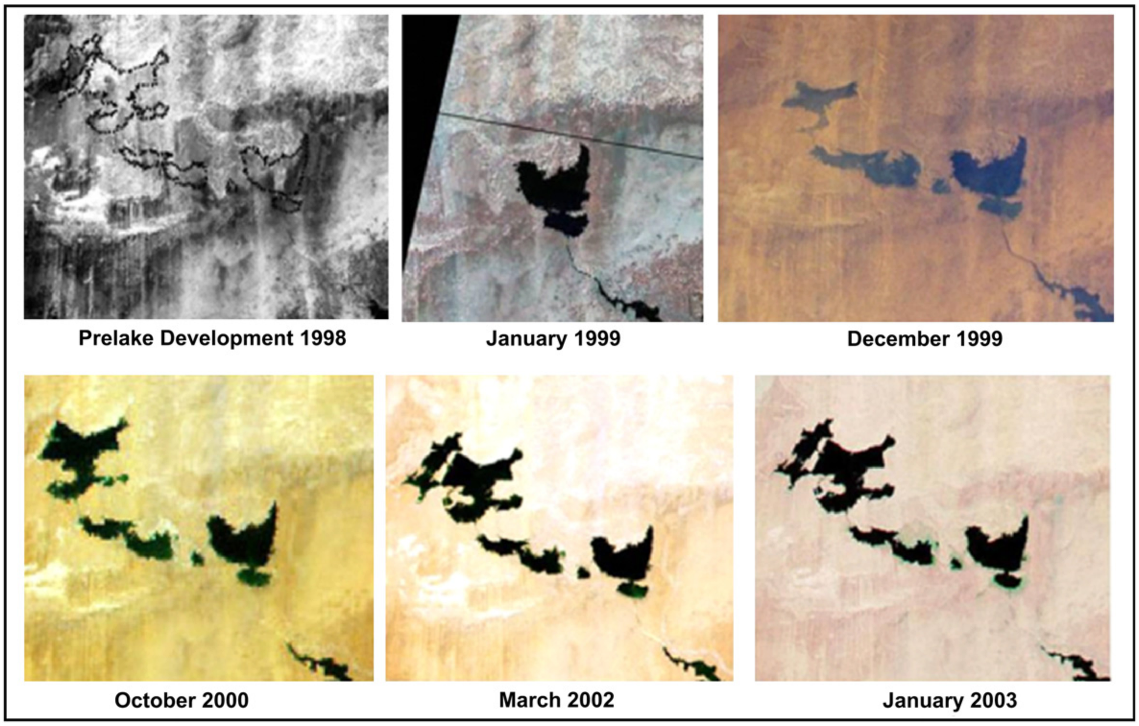

Figure 13 Temporal (1998–2003) satellite data showing the development of the Tushka lakes.

In Wadi Asyuti, all of the collected groundwater samples (eight samples) showed depleted isotopic compositions (δD: $-34.68‰$ to $-51.96‰$). These depleted compositions, undetectable tritium (<1 TU), and discharge temperatures (27–32 °C) indicatethat these waters are paleowaters, largely derived from the underlying Nubian sandstone. In this area, the Nubian sandstone is found at depths exceeding 1 km; thus, the groundwater must have ascended via deep-seated faults. Three major subvertical, northwest-trending faults were identified along cross section B-B′ (inset Figure 14) using geophysical data and utilizing information extracted from drilling (RIGW 1993). The thickness of the alluvium aquifer significantly increases (to more than 300 m) from the northeast to the southwest. The location of these subvertical faults plots along northwest-trending structural discontinuities that could be readily identified on Landsat TM images and on digital topography. Figure 14 is an overlay of Landsat TM data over digital elevation, an image that integrates and displays information contained in the two datasets. Inspection of the image shows that topographic expressions (valleys and grabens) mark the projected extensions of the traces of three northwest-trending faults into the adjacent mountains. A two-dimensional groundwater flow model was constructed and calibrated against head data from 19 wells to assess the discharge and to demonstrate a replicable model for similar reservoirs. Results point to a significant contribution to the Asyuti groundwater system from rising Nubian groundwater ($3.19 \times 10^7\,\mathrm{m^3\,yr^{-1}}$: 75% of incoming flow) and point to similar settings for large-scale natural discharge along the length of the River Nile in Egypt and Sudan and along the Gulf of Suez.

5.20.10 Scenarios for Recharging the Nubian Aquifer

It is suggested here that Egypt could develop sustainable agriculture practices in the Western Desert by channeling the encroaching Lake Nasser waters in high flood years across the western plateau reaching the lowlands west of the plateau that are largely underlain by Nubian Sandstone. This could be accomplished by deepening the canals joining the natural depressions and extending the deepened canal system across the western margin of the plateau. In high flood years, the channeled excess Lake Nasser waters will flow down gradient along Darb El Arbeen toward the Baris, Kharga, and Dakhla oases (Fig. 10b), where the water could be used for sustaining and expanding the agricultural communities and for recharging the fossil waters of the Nubian Aquifer in these areas. This solution will minimize water loss to direct evaporation (39% excess water) and address the steady decline (up to $2\,\mathrm{m\,yr^{-1}}$) in groundwater levels in the oases that have been recorded for the past 60 years. Excess Lake Nasser waters could be channeled via canals, piped, or even allowed to flood Darb El Arbeen (Fig. 10b). Prior to the construction of the Aswan dam, Nile waters flooded the Nile banks, depositing soils and bringing nutrients to the flooded areas; following the recession of the waters, the Egyptian peasants cultivated these rich soils. Similar, but not necessarily identical, scenarios could be adopted in the Western Desert. However, careful consideration must be given to protection or relocation of existing infrastructures in these areas, and to the prevention of aquifer contamination by agricultural and industrial chemicals in the surface waters.

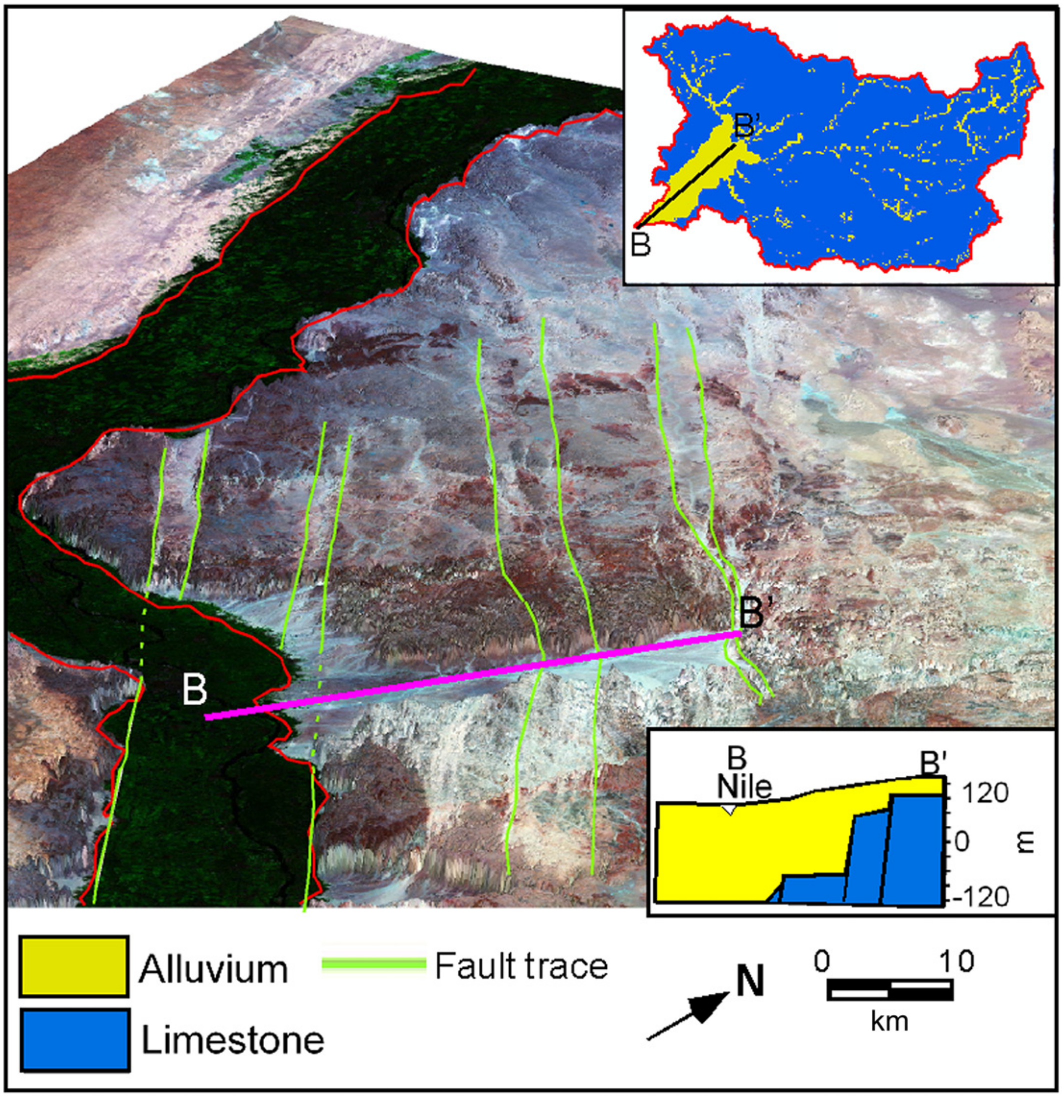

Figure 14 Landsat TM image (false color image) for the Wadi Asyuti area and surroundings draped on digital elevation data. Upper right inset: Asyuti watershed with network of channels flowing from the Red Sea hills toward the Nile River valley; main rock units are Quaternary alluvial deposits (yellow) and Tertiary limestone (blue). Lower right inset: cross section along traverse B–B′ (simplified from Rossignol-Strick, 1983). Topographic expressions (valleys and grabens) mark the projected extensions of the traces of northwest-trending faults identified by drilling and by geophysical methods into the adjacent mountains. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this book.) Source: Modified from Sultan, M., E., Yan, N., Sturchio, et al. 2007. Natural discharge: a key to sustainable utilization of fossil groundwater. *J. Hydrol.*, **335** (1–2), 25–36.

5.20.11 Development of Realistic Groundwater Flow and Age-Mass Transport Models for the Nubian Aquifer

The majority of the Nubian Aquifer models apply a simple piston flow system with one recharge source and are calibrated against current hydraulic heads (e.g., Brinkmann et al. 1987; Euroconsult-Pacer 1983; Soliman et al. 1998). Development of more realistic models for the Nubian Aquifer System could assist in understanding complex flow systems and in predicting hydrologic responses to anthropogenic controls and projected climatic changes. The model could also be used to assess the impacts of various water resource management schemes. The advocated model might incorporate a regional flow system initiated by continuous recharge from mountainous areas in Chad and along the Red Sea hills, localized historical recharge from surface-water infiltration during wet climatic periods (refer to Sections 5.20.1 to 5.20.3), and discharge through a chain of oases in the Western desert and along the deep fault systems that bound the Nile Valley and the Gulf of Suez (Yan et al. 2004; Sultan et al. 2007). Transient flow models should be constructed to run for hundreds of thousands of years given the known ages of the groundwater (up to 1 million years) (Sturchio et al. 2004). Because flow simulations for hundreds of thousands of years that are calibrated against current hydraulic heads are probably unreliable at best, a model that is capable of simulating the groundwater age distribution and the ages of the paleochannels would be more representative of the system.

The construction and calibration of the advocated model may require (1) development of a conceptual model that integrates geological, hydrogeologic, geochemical, and remote-sensing data listed in this study and from all available other sources for the Nubian Aquifer System; (2) construction of a transient numerical flow model that accounts for the continuous recharge from the south (Chad) and from the Red Sea hills, for the local intermittent recharge during wet periods, and for the discharge in the oases and along the River Nile; and (3) collection of a comprehensive groundwater age data set across the Nubian Aquifer and simulation of observed groundwater age distribution using the Goode's age-mass advection–dispersion–diffusion transport equation.

The developed conceptual models for the Nubian groundwater system should account for the distribution of delineated subbasins, paleo-recharge areas, paleodrainage patterns, paleochannel sedimentary systems, discharge areas, and groundwater ages in conjunction with geological stratigraphic and hydrological data. The conceptual model should address lateral and vertical discontinuities that significantly affect the flow system. A large-scale three-dimensional numerical flow model could be constructed to cover the entire Nubian Aquifer. The model should account for the observed vertical and lateral variations in the lithologic sequences of the Nubian Aquifer System (four major water-bearing horizons: A through D) and their corresponding hydraulic parameters. The hydrogeological parameters (e.g., hydraulic conductivity, storage coefficients, aquifer thickness) can be extracted from many published data (Euroconsult-Pacer 1983; Hesse et al. 1987; WPRP 1998).

The time period for the transient flow model should be constrained by the existing constraints on the timing of pluvial periods for the last 400 000 years (Crombie et al. 1997; Crombie et al. 1999; Rossignol-Strick 1983; Sultan et al. 1997; Szabo et al. 1995). Several intermittent periods of wetter conditions occurred during the last 400 ka, with the most recent recharge occurring between 9.5 and 4.5 kyr B.P. Arid conditions may have prevailed between about 10 and 20 ka (Brinkmann et al. 1987; Pachur and Roper 1984). Under semiarid conditions between 25 and 40 ka, groundwater recharge from an estimated 200–250 mm rainfall is <30 mm yr^{-1} (Hesse et al. 1987; Pachur and Kropelin 1987). These precipitation rates were inferred from the distribution of prehistoric floral and faunal remains (Hassan 1996; Kowalski et al. 1989). For modeling purposes, our findings, these published data sets, and other published data sets could be used to define (1) timing of historic stresses for the transient flow model(s), corresponding to the known periods of wet and dry climate conditions, and (2) precipitation and recharge during these periods. Areas of continuous recharge should be limited to the southernmost mountainous area (in Chad) and along the Red Sea hills. The current recharge rates in these areas should be estimated using the continuous simulator. Local area(s) that witnessed intermittent recharge during previous wet climatic periods in southern Egypt and northwestern Sudan can be defined from the distribution of Nubian Sandstone outcrops and the inferred paleochannel sedimentary system. Discharge in the oases of the Western Desert and along the Nile and the Gulf of Suez fault complexes is also an important model element.

An age-mass transport model (Goode 1996) can be constructed to simulate the observed groundwater age distribution. The age-mass is the product of water mass and its age. The initial age-mass for the entire aquifer system is highly uncertain. However, for a 400 000-year simulation, the groundwater age in most of the investigated area is probably insensitive to the initial age. The simulated groundwater should be calibrated against the ages of groundwater samples. The calibration can be accomplished via an iterative process of adjusting specific flow and mass transport parameters, such as hydraulic conductivity, recharge rate, recharge duration, conductance for drains in oases and seepages along the Nile Valley, evaporation rate, longitudinal and vertical dispersivities, and diffusion coefficients to achieve the best agreement. The advocated model will provide an effective tool to investigate the responses of the aquifer system to climate, water extraction scenarios, anthropogenic factors, and various water resource management strategies.

5.20.12 Findings

If we were to generalize our findings in Egypt and in northern Sudan (Selima sheet catchment) to the remaining parts of the Nubian Aquifer and take into consideration the existing meteorological data, GRACE gravity data, and isotopic and geochronologic data for groundwater, remote sensing and geophysical data, and our simulations from hydrologic models, the following picture would emerge: (1) the Nubian Aquifer System is more likely to be formed of a number of discrete subbasins that are largely disconnected from one another, and within each of these postulated subbasins the ages of the groundwater will increase along the flow direction; (2) during wet climatic periods, precipitation was widespread across the entire Nubian Aquifer and autochthonous recharge was occurring within each of the subbasins in areas where the Nubian sandstone crops out; (3) autochthonous paleo-recharge was probably occurring through transmission losses from paleodrainage systems, currently buried under the sand sheets; (4) precipitation has been continuous over Chad and surrounding areas and probably intensified during the wet climatic periods; (5) the Nubian Aquifer is receiving modern recharge on a regional scale in the south (Chad and Sudan) and locally in areas in the north (e.g., Sinai) where the exposed aquifer rocks receive relatively large amounts of precipitation that are channeled by streams or are precipitated directly over the Nubian outcrops; (6) the construction of the Aswan High Dam raised the surface-water levels in Lake Nasser behind the dam, reversed groundwater flow direction, and recharged the aquifer with $10^{11}\,\mathrm{m}^3$ of Lake Nasser's water throughout the period 1975–2001; (7) many of the areas of natural discharge within the Nubian Aquifer have gone undetected, and discharge of the Nubian Aquifer is largely occurring along the fault complex that defines the River Nile and the Gulf of Suez where ascending groundwater accesses deep-seated fault systems and discharges into relatively thick alluvial aquifers proximal to these two fault complexes; and (8) analysis of interannual mass variations from monthly GRACE solutions that span the period from April 2002 through November 2010 indicated near-steady-state solutions in the south (Sudan: $0.69 \times 10^9\,\mathrm{m}^3\,\mathrm{yr}^{-1}$, $0.8\ \mathrm{mm\ yr}^{-1}$; Chad: $-0.12 \times 10^9\,\mathrm{m}^3\ \mathrm{yr}^{-1}$, $-0.9\,\mathrm{mm\,yr}^{-1}$) and in Libya ($-0.39 \times 10^9\,\mathrm{m}^3\ \mathrm{yr}^{-1}$, $-1.1\,\mathrm{mm\,yr}^{-1}$), and declining water supplies in the north (Egypt: $-2.35 \times 10^9\,\mathrm{m}^3\,\mathrm{yr}^{-1}$, $-3.5\,\mathrm{mm\,yr}^{-1}$) that are apparently largely related to progressive increase in extraction rates with time.

Future work should concentrate on research activities to enable the following: (1) further examination and refinement of our preliminary model/concept in Egypt, (2) examining the relevance of the developed models/concepts to other parts of the Nubian Aquifer System, and (3) developing realistic numerical models for the Nubian Aquifer System that are constrained by published and newly acquired data.

We provided two test cases to address sustainable management of the Nubian water. The first estimates the average annual recharge for the Nubian Aquifer in Sinai in an attempt to identify sustainable extraction in this area. Sustainable use of the Nubian Aquifer water in areas of relatively high precipitation could be attained if extraction from the aquifer did not exceed the average amounts of modern recharge for the same time period. The amount of recharge could be enhanced by the construction of dams in areas of relatively high precipitation to enhance recharge and to decrease losses to runoff. The second approach is suggested to supplement the fossil groundwater extracted from the aquifer and is proposed for areas where temporal mass variations indicate progressive depletion of the aquifer with time due to excessive extraction. The approach calls on channeling excess Lake Nasser water in years of high flood to the Western Desert to replenish the progressively depleted Nubian Aquifer in this area. Long-term strategies for sustainable management of the Nubian Aquifer will require the construction of improved hydrologic models that can account for the geological, hydrogeologic, geochemical, geochronologic, geophysical, and remote-sensing observations and findings discussed here and that can simulate the observed groundwater age distribution. These models should have the necessary resolution for predicting the near-term effects of extraction, artificial recharge, and potential for aquifer contamination by recharging water, as well as the longer-term effects of climate.

5.20.13 Implications for the Vulnerability of the Nubian Aquifer

Studies, such as those presented and proposed here, are required if we are to address the projected vulnerabilities of the Nubian Aquifer over the next few decades. The Nubian Aquifer is vulnerable from a number of perspectives. The increasing population in the region, as well as effects of climate and its resultant impacts on sea level and the water cycle dynamics, is predicted to create substantial demand for increased production of groundwater from the Nubian Aquifer System. We have shown that even at current rates of extraction, the Nubian Aquifer is being gradually depleted by extraction and natural discharge.

The population in Egypt is expected to approach 100 million by the year 2025 with the fresh water supply decreasing to 337 m^3 per capita (AbuZeid and Hefny 1992). Considering that about 80% of Egypt's water use is already consumed by agriculture, the production of sufficient food for the population will necessitate improvements in agricultural water use efficiency and may require the development of new agricultural lands that need to be irrigated with groundwater. Furthermore, as upstream population in the Nile Basin continues to grow, there could be increased demand on the Nile River before it reaches Egypt. The 1959 treaty that guarantees Egypt an annual Nile water allotment of $55.5 \times 10^9\ \mathrm{m}^3$ is now being challenged by River Nile Basin countries in the upstream. The gradual increase in global temperatures will increase evaporative losses from the surface of the river and Lake Nasser. Furthermore, many global climate model scenarios for the Nile Basin region predict a net decrease in Nile flow (Strzepek et al. 2001).

A gradual rise in sea level is predicted as a consequence of global warming. In Egypt, most of the agricultural production occurs in low-lying lands of the Nile Delta, and inundation of delta farmlands will create an urgent need for additional agricultural land development and irrigation to ensure food supply to the population. As much as 26% of the habitable land in the Nile Delta could be lost to sea level rise and delta subsidence by the year 2100 (Milliman et al. 1989). This massive land loss will cause large-scale migration to presently undeveloped land, and much of this development will have to occur outside the Nile Valley in regions dependent on groundwater for irrigation. The increasing population, along with increasing land use for agricultural and industrial production, will contribute to an increase in polluted wastewaters. Improper wastewater treatment practices could result in contamination of groundwater aquifers.

Mitigation of the effects of population increase, climate, and sea level rise can be achieved in part by increasing water use efficiency and promoting water conservation and recycling. However, it is inevitable that the demand for fresh water will outpace the supply, and new sources of fresh water will be imperative. The extraction of Nubian Aquifer groundwater is certainly destined to substantially increase as demand grows. Increasing amounts of groundwater extraction may eventually aggravate transboundary water disputes (Maxwell 2011). Armed conflict has already occurred for decades in the Aouzou Strip along the Chad-Libya border, in part related to Nubian water usage. The respect of sovereign rights to water resources within national boundaries is often at odds with the concept of shared transboundary resources such as the Nile River and the Nubian Aquifer.

5.21.1 Introduction

Many areas in Africa are already recognized as water stressed and highly vulnerable to climate impacts mainly because of having climates that are among the most variable in the world on seasonal and decadal time scales. Estimates indicate that one-third of the African people are already living in drought-prone areas and 220 million are exposed to drought each year (UNFCCC 2007). It has been already recognized that many factors contribute to compounding the vulnerability and will have negative effects on the continent's ability to cope with climate and other threats (UNDP 2006). Examples of such factors are poverty, illiteracy and lack of skills, weak institutions, limited infrastructure, lack of technology and information, low levels of primary education and health care, poor access to resources, low management capabilities, and armed conflicts. These factors contribute to low adaptive capacity and societal resilience to changes and an overexploitation of land resources in Africa. UNFCCC (2007) reports that Africa will face increasing water scarcity and stress with a subsequent potential increase of water conflicts, as almost all of the 50 river basins in Africa are transboundary.

The situation in eastern Africa, and particularly Ethiopia, is no different from the continental situation. There is mounting observational evidence indicating how Ethiopia is highly vulnerable under both nonclimatic and climatic drivers. This paper addresses the water resources vulnerability of Ethiopia and presents an account of the observational evidence of the contextual vulnerability that may be considered representative of the greater Eastern Africa region composed of Somalia, Sudan, and Kenya.

5.21.2 Ethiopia in Eastern Africa: Climate and Water Resources

5.21.2.1 Location in East Africa

Eastern Africa is geographically divided in to three subregions, that is, Horn of Africa, which includes Ethiopia, Eritrea, Sudan, Djibouti, and Somalia; the Great Lakes region, which includes Uganda, Kenya, Tanzania, Rwanda, and Burundi; and the Indian Ocean islands of Comoros and Seychelles (**Figure 1**). The Horn of Africa has more desert and semidesert regions, whereas the Great Lakes region is known to have more forest area. The low-lying part of Northern Kenya and Somalia are relatively extremely dry, whereas the rainfall gain increases toward the south. Temperature in eastern Africa is generally moderate except in the hot and generally humid costal belts. Water availability is determined mainly by rainfall amounts. The amount of rainfall in Eastern Africa varies spatially and temporally. The Great Lake subregion receives more rainfall than the Horn of Africa. The rainfall amount varies seasonally as dry season, intermediate, and rainy season. Moreover, the rainfall has experienced an overall decline in Eastern Africa since the 1960s (Schreck and Semazzi 2004). This has caused periodic drought and thus water scarcity, which have resulted in famine in Eastern Ethiopia, Kenya, and Somalia land (USAID 2005; Cheung et al. 2008; USGS and USAID 2010).

Ethiopia is located almost at the center of the Horn of Africa (**Figure 1**) having a highly rugged landscape. The Great Rift Valley divides the country into the central/western highlands, which run from north to south, and the Eastern highlands (WAPCOS 1990). The highlands on each side give way to vast semiarid lowland areas in the east and southern part of the

country, exposing these areas to extreme climate variability and recurrent drought and famine.

5.21.2.2 Climate and Water Resources

Ethiopia has essentially a rainfed agricultural system where more than 83% of the population depends on subsistence agriculture. Although rainfall plays a great role as a vital water resource for securing nearly the entire food production of the country, the temporal and spatial distribution is extremely variable and uneven. The spatial mean annual rainfall distribution over the country varies above 2000 mm over some pocket areas in the southwest to less than 250 mm over the vast areas of Afar and Ogaden low lands in the eastern part of the country (NMSA 1996, 2001) (Figure 2). Most of Ethiopia receives between 50 to 100% of its annual rainfall during the rainy season from June to September during which 90% of food production is secured.

Studies estimate that the country has an estimated annual internal renewable water in the order of 122 billion cubic meters (BCM), excluding the groundwater potential from its 12 river basins (WAPCOS 1990). Groundwater contribution is believed to be in the order of 2.6 BCM. Less than 5% of the renewable water resources is put to any beneficial or strategic use in the country. The three river systems contributing to the Nile basin (Blue Nile, Baro–Akobo, and Tekeze), which comprise 30% of the total land areas, constitute nearly 70% of the total internally renewable water amount. The four major river basins originating from western highlands (the above-mentioned Nile tributaries and Omo–Gibe) constitute about 84% of the total volume of flow generated in Ethiopia. This is generated only from 38% of the total area of the country (western part). The remaining 62% of the country generates only 16% of the total internally renewable water. The main river basins that originate from the central and eastern parts of the country (Awash, Wabi-Shebelle, and Genale–Dawa) occupy about 43% of the country's area, but their combined runoff generation constitutes only 11% of the total runoff generated within the country. The Blue Nile river basin has the largest surface water generation with about 50 BCM of annual flow, followed by the Baro–Akobo and Omo–Ghibe basins. As shown in Figure 3 and Table 1, the water availability of the country is highly uneven and skewed to the western part of the country.

5.21.3 Historical and Observational Evidence of Climate Variability

The recent history of Ethiopia is remembered by the recurrence of hazardous droughts in many parts of the country (Shanko and Camberlin 1998; NMSA 2001; Funk et al. 2003; USAID).

Although the historical social and economic impacts of all these hazards are not systematically well documented, the impacts of the most important ones namely, droughts and floods, have been partially documented by Disaster Prevention and Preparedness Agency (DPPA) on NAPA (2007) since 1543 (Table 2). Catastrophic drought/famine has been recorded over the entire country, with major ones being concentrated in the northeast and southern part of the country. The frequency and magnitude of the occurrence has increased over time (NMA 2007). Actual figures indicate that the number of affected people has increased from 1.5 million in 1965 to over 13 million in 2002–03. Drought occurs anywhere in the world, but its damage is not as severe as in Africa in general and in Ethiopia in particular mainly because of low adaptive capacity (e.g., very few storage facilities).

The other climate-related hazards that affect Ethiopia from time to time are flash and seasonal river floods. Areas in the Afar region along the Awash river, in the Somali region

along the Wabi 26 Shebelle river and in the Gambela region along the Baro–Akobo rivers (Figures 1 and 3), in the southern region along the Omo–Gibe rivers, as well as the Bahirdar Zuria and Fogera areas along the Abbay river in the Amhara region are prone to seasonal river floods (Endalkachew et al. 2004; quoted in NMA p. 37). Major floods that caused loss of life and property occurred in different parts of the country in 1988, 1993–96, and 2006. For example, during the 2006 rainy season, flood caused a major disaster to life and property (NMA 2006). More than 250 people died, about 250 people were unaccounted for, and more than 10 000 people became homeless. In the south, more than 364 people died and more than 6000 people were displaced from about 14 villages because of flooding of the Omo river. Widespread flooding damage occurred in many parts of the country that had no past history of flooding. More than 16 000 people were displaced in West Shewa, while similar situations have been recorded in Afar, Western Tigray, Gambella Zuria, and the low-lying areas of Lake Tana. In terms of loss in property and livestock, the DPPA has estimated that over 199 000 people were critically affected. More than 900 livestock drowned over south Omo. A total of 2700 heads of cattle and 760 traditional silos were washed away (World Food Program, WFP). Over tenth of millions of dollars worth of property and infrastructure was destroyed by the flood that affected the Dire Dawa.

Observational evidence from historical records of temperature and precipitation spanning 1971–2000 for 42 selected stations (NMA 2007) shows that the country has experienced both dry and wet years. However, the overall trend of aerial average annual rainfall of the country has remained more or less constant (Figure 4). This implies that the aerial annual rainfall cannot be a proxy indicator of the extreme variability of rainfall over the eastern and northern parts of the country, indicating the divergent climatic situation of the country. For instance, the longer record available for the capital Addis Ababa (1898–2002) also shows no clear rainfall trends (Conway et al. 2004). Other stations in the Rift Valley not far from Addis Ababa exhibit declining trend, whereas stations toward eastern Ethiopia exhibit extreme

variability (unpublished Awash hydrometerological report, 2012). Past studies have shown that there is a link between the El Niño and La Niña phenomena and the Ethiopian rainfall variability (Haile 1988; Korecha and Barnston 2007; Gissila et al. 2004).

The year to year variation of annual minimum temperatures expressed in terms of temperature differences from the mean and averaged over 40 stations (Figure 4) shows that the recent years are warmer compared to the early years. Overall, observation shows a warming trend of about 0.37 °C per decade. An unresolved issue, however, is explaining this trend. Candidates include added greenhouse gases (e.g., CO_2), which produces less radiative cooling at night (Steeneveld et al. 2011); regional landscape changes (Pielke et al. 2011); and deterioration of the spatial representativeness of the surface observing sites (e.g., Fall et al. 2011).

Such evidence from historical data does not, however, provide adequate information on the condition of the current vulnerability of Ethiopia. For instance, it has been documented by many researchers (e.g., Meze-Hausken 2004) that the observational record and the drought perception do not match the realities on the ground. As shown in Figures 5 and 6, the year 1979, which could be defined as a drought year in meteorological terms, was not regarded as such a drought year according to public perception. The year 1984 had a below-average total precipitation similar to the year 1979. However, 1984 'considered' a severe drought year, according to public perception (Figure 6). Therefore, it is believed that additional contextual factors (that are more 'bottom-up'), such as increase of rural population, and land degradation, resource vulnerability, poverty, etc. have likely contributed to this perception of the severity of a drought and dictated the population's resilience to it.

5.21.4 The Contextual Vulnerability Factors

5.21.4.1 Population Growth and Multidimensional Poverty

The Eastern Africa population is continuously growing with the annual growth rate greater than 2.2%. According to the United Nations Development Programme (UNDP), the 2011 Human Development Index (HDI) reported that Ethiopia is the second populous country in the continent and has a population of 85 million as of 2011. This population is projected to become about 120 million by 2030. More than 83% of the population is rural and lives largely as subsistence rainfed agricultural farmers. About 88% of the population is affected by multidimensional poverty, of which about 72% live under severe poverty (UNDP-HDI Office 2011) (Multidimensional poverty index (MPI) is a weighted poverty index that integrates the indicators of deprivations of education, health, and living standard. Each indicator carries 1/3 weight (UNDP-HDI Office, 2011)). Figure 7 shows the regional population of Eastern Africa reaching to over 300 million by 2025 (van de Giessen 2011). This adds additional pressure on land and water resources of the region, and the population remains more vulnerable than ever to the natural shocks from climate variability.

A study conducted by Deressa et al. (2008) examined indicators of vulnerability across 7 of the 11 Regional States of Ethiopia: Afar; Amhara; Beneshangul Gumuz; Oromia; the Southern Nations, Nationalities, and People's Region (SNNPR); Somali; and Tigray (Figure 8). The study calculated vulnerability to climate by region as the net effect of sensitivity, exposure, and adaptive capacity. Results indicate that Afar, Somali, Oromia, and Tigray are relatively more vulnerable to climate than the other regions. The vulnerability of Afar and Somali (eastern part of Ethiopia) is attributed to their low level of rural service provision and infrastructure development. Tigray and Oromia's vulnerability to climate can be attributed to the regions' higher frequencies of droughts and floods, lower access to technology, fewer institutions, and lack of infrastructure. SNNPR's lower vulnerability is associated with the region's relatively greater access to technology and markets, larger irrigation potential, and higher literacy rate (Figure 8).

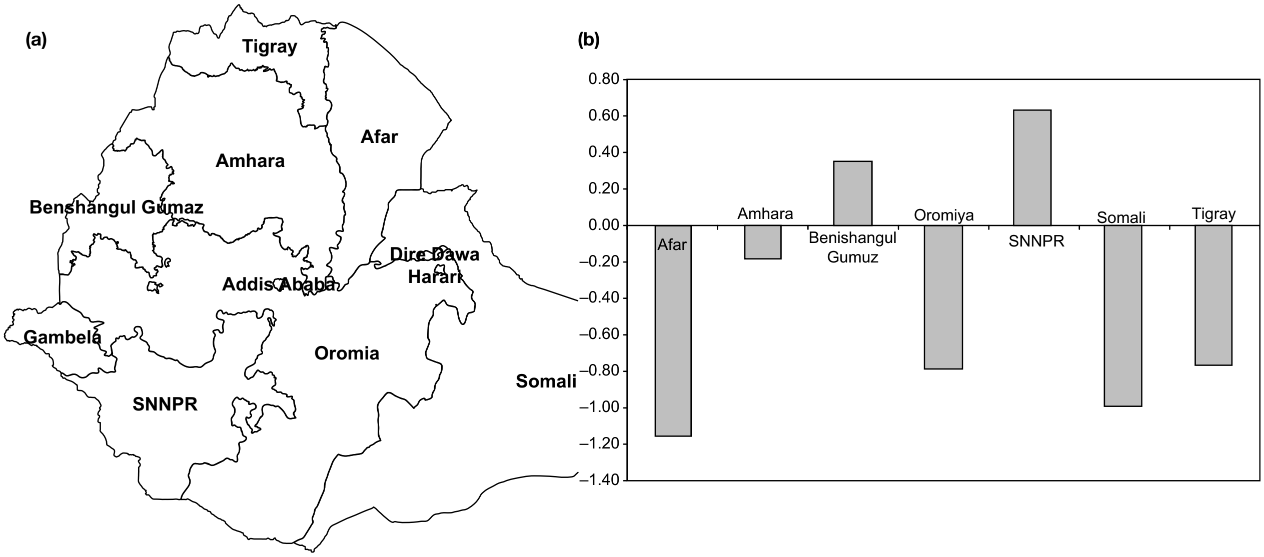

Figure 8 (a) The spatial vulnerability of the seven main regional states of Ethiopia. The negative *y*-axis in (b) represents the ‘vulnerability’ index with 0 being no vulnerability. Positive *y*-axis means negative vulnerability or positive resilience. Reproduced from Deressa, T. T., R. M. Hassan, and C. Ringler, 2008: Measuring Ethiopian farmers’ vulnerability to climate change across regional states. International Food Policy Research Institute (IFPRI) Discussion Paper, 00806, Washington, DC. [Available online at http://www.ifpri.org/sites/default/files/publications/ifpridp00806.pdf.] Accessed on 15 August 2011.

5.21.4.2 Dependence on Rainfed Agriculture

As mentioned earlier, an estimated 83% of the population is dependent on rainfed agriculture and lives in rural areas. Agriculture employs 80% of the labor force and accounts for 50% of the GDP. When the resources base (which is rainfall) gets degraded because of climate and hydrological variability, manifested as dry spells, droughts, and floods, a profound impact on the production of agriculture has been noted. Consequently, the entire population has become vulnerable to food insecurity (famine). The destructive nature of droughts and floods is now becoming endemic with increasing occurrence compared to four decades ago because of the low adaptive capacity. In terms of economic cost that World Bank estimates show, one-third of the economic gains can easily be lost through the impacts of hydrological variability (Figure 9). Generally, water as a natural resources base for food production is tied up with subsistence level farming (usually farmlands less than 1 ha). Almost everybody produces his/her own food as well as food for the few additional urban residents. Therefore, the complex relationship of water–food nexus is highly fragmented and requires an adaptation approach that is highly flexible and contextual.

5.21.4.3 Land Degradation and Desertification

Land degradation here mainly refers to the loss of life-supporting land resource through soil erosion, desertification,

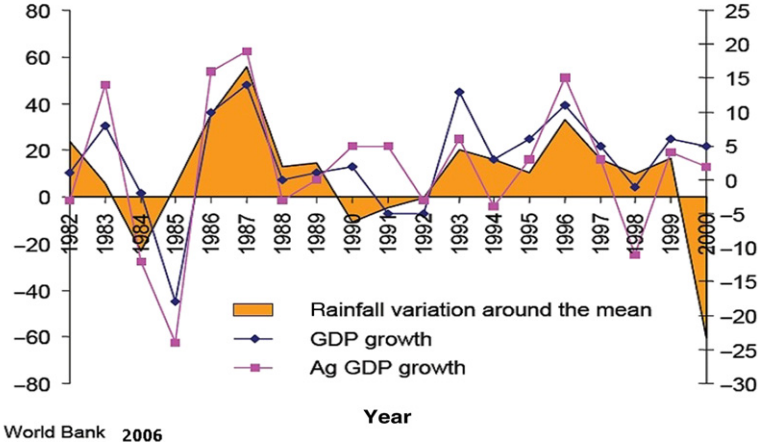

Figure 9 Rainfall, GDP, and agricultural GDP (Ag GDP) of Ethiopia. salinization, acidification, etc. Deforestation accounts for the major land degradation problem as it results in severe soil erosion, flood, and loss of fertile soil. Eastern Africa including Ethiopia has experienced moderate to severe land degradation problems as shown in Figure 10. The figure shows that very severe degradation occurred in northern Ethiopia (the food basket area), Sudan, and part of Somalia. For instance, over a period of time, Ethiopia's original forest cover was reduced from 65% to a mere 2.2% of the total country's area coverage (Berry 2003). This has resulted in reduction of soil water holding capacity of the known spring water sources and base flow of streams, which are known to be vital sources of residual soil moisture and domestic water sources. Desertification, on the other hand, generally occurs after a prolonged degradation of land. Desert areas cannot support life for long as the available water can hardly support life. Farmers in Ethiopia, Somalia, and Kenya are therefore more vulnerable to undergoing desertification than others.

5.21.5 Bottom-Up Adaptation Approaches to Climate Vulnerability

5.21.5.1 The Proposed Adaptation Action Plan

Adaptation to climate variability is now one the main theme for African nations. It has been shown that many countries in the continent have developed National Adaptation Programmes of Action (NAPAs). Most of these NAPA documents have direct reference to the coarse-scale IPCC global climate change projections output, and reference to the local situation is very limited. Consequently, most of the recommended adaptation options neither provide location-specific contextual adaptation options geared to the local situations nor consider that the IPCC global climate change projections have not demonstrated any skill at predicting *changes* in regional climate statistics (Pielke et al. 2012). For instance, the NAPA adaptation recommendations for Ethiopia provided a mix of 26 potential adaptation options before even classifying the vulnerable resources, the type of vulnerability, and priority area of specific adaptation sites. It is true that most of the climate-related vulnerabilities will likely affect the entire country and that the national recommendation may subscribe to many of the 26 recommended adaptation options (Table 3).

However, the productive area of Lake Tana subbasin in the northeastern part of Ethiopia is more vulnerable to flash floods than drought. It requires specific adaptation solution of flood protection, flood early warning system, rather than drought mitigation options per se. Therefore, such kind of local-scale qualification of the priorities is required further in Ethiopia. In this case, the bottom-up adaptation approach is more realistic as it provides specific, cost-effective, and at site adaption options that can provide measureable solutions and framework for studying the interaction of resources with the society locally.

Table 3 Recommended adaptation measures for Ethiopia

Serial number	*Specific adaptation measures*
1	Promoting drought/crop insurance program in Ethiopia
2	Realizing food security through multipurpose large-scale water development project in Gennale Dawa basin
3	Community-based development and commercialization of nontimber forest products (gum Arabic, myrrh, and Frank incense)
4	Community-based rehabilitation of degraded ecosystems in selected parts of Ethiopia
5	Propagation and commercial-scale cultivation of wild essential oil crops
6	Establishment of center for propagation and commercialization of traditional herbal medicinal plants
7	Establishment of acacia woodland nature reserve in the Ethiopia rift valley system

5.21.5.2 A Paradigm Shift in Climate Adaptation in Ethiopia

5.21.5.2.1 Implementation of Water Storage Continuum

In Ethiopia, like other Eastern Africa countries, the economy and livelihood of the society is highly correlated with rainfall variability. Compounded with the level of poverty, demographic rise, and low level of adaptive capacity and resilience, there is now no doubt that an adaptation option in Ethiopia and Eastern Africa will be the best approach that dampens the impact of rainfall variability through storing water in available storage media whether as soil moisture storage, ponds, or dams. There is huge potential to rethink access to water availability of water storage in all places and at scale commensurate to the relevant factors of topography, climate, hydrology, and soil. Ethiopia is one of the countries with the lowest per capita water storage availability in the world with 43 m^3 per capita, in contrast to 750 m^3 per capita in South Africa and about 6150 m^3 per capita in the United States (World Bank 2006). This underscores the necessity of building storage facilities across the nation. This requires understanding the storage development niche of each area and of the variety of storage options with regard to climate, topography, hydrology, and capacity.

Johnston and McCartney (2010) have provided a paradigm for natural as well as artificial storage as a continuum of storage facilities to be implemented as a bottom-up adaptation option. The storages include a variety of forms incorporating small-scale soil moisture storage through water harvesting ponds to large-scale water storages (such as small to large dams): natural wetlands, soil moisture, groundwater aquifers, ponds/small tanks, and reservoirs (Figure 11). There appears no other way, other than introducing such strategic storage options, to reduce the vulnerability of the water resources in Ethiopia. Especially, the untapped surface water resources, which are estimated to be in the order of 122 BCM, can be a buffer to offset the increasing variability of food and water insecurity in Ethiopia.

5.21.5.2.2 Social Protection Schemes: Productive Safety Net Programme (PSNP)

The identification of the type of storage requirement and its implementation will require time. In the interim, social protection schemes are vital as a transition mechanism to help societies adapt to newer approaches. There is already a functioning social protection scheme in Ethiopia called Productive Safety Net Program (PSNP) as a transitory mechanism (Devereux and Guenther 2007). PSNP is the largest social protection scheme in Africa outside of South Africa's social grants schemes. The PSNP delivers social transfers to some 8 million Ethiopians each year, either through 'public works' activities or as 'direct support' for households that are labor constrained. Capitalizing on the public works component, social protection schemes can be used to involve the productive labor force in building community assets used for adaptation purposes such as water harvesting structures, tree planting, and water and soil conservation activities. There is already an

encouraging sign in northern Ethiopia that natural springs have started to reappear, water and soil conservation structures have yielded moisture enhancements, and farmers have been reported to graduate from the social protection schemes. Therefore, social protection schemes are suggested as a bridge to building adaptation assets in chronically moisture-constrained areas of southeastern, eastern, and northern parts of Ethiopia.

5.21.5.2.3 Weather-Indexed Drought Insurance

Ethiopian smallholders face persistent risks of drought, against which they are unable to insure, because of missing insurance markets. According to a review by Devereux and Guenther (2011), experience from other countries suggests that insurance delivers both social protection for farmers (a guaranteed safety net against harvest failure) and agricultural growth (confidence to take moderate risks such as investing in fertilizer or high-yielding varieties). Missing insurance markets is a common feature throughout Africa and is explained by such factors as low incomes of farming households, information asymmetries, moral hazard, and the covariate nature of agricultural risks. Therefore, it is suggested that drought insurance be implemented not as a stand-alone blanket measure to reduce drought vulnerability, but in areas where mild to moderate drought occurs and productivity is high. This can protect the main base of the food basket of the country during the national drought periods.

5.21.5.2.4 Extreme Hydrological Events, Forecasting and Early Warning Systems

Institutionalized forecasting and early warning system is one of the technological options that can be implemented in the region. There is evidence of preparedness and reduction of catastrophes in the flood and drought areas of the region as a result of forecasting and early warning system. Thus, investing in such early warning systems can be incorporated as part of adaptation package that covers from small-scale to large-scale water resources vulnerability reduction. It can be used to forecast large-scale drought for rainfed agriculture to inflow forecasting for reservoir operation for hydropower and irrigation systems in the region.

5.21.6 Conclusion

Historical evidence shows that the eastern parts of Africa are highly vulnerable to the impact of variability from climate. Most parts of Ethiopia, in particular, have experienced pronounced effects of drought over the past 40 years. The nonclimatic drivers such as population explosion, land and water degradation, etc. collectively expose the country further to vulnerability.

Recent studies also show that the region is highly sensitive to changes in precipitation and temperature. Investigations reveal that a 1-unit change to precipitation variability can significantly affect the freshwater availability by about 2 units. Such high sensitivity of precipitation to fresh water supply is another critical dimension of climate vulnerability of the region. With respect to the future, it currently remains highly uncertain as to what should be the most effective adaptation strategy to address these vulnerabilities.

Compounded with the level of poverty and population rise, the best adaptation option in Ethiopia and eastern Africa is to improve adaptive capacity and resilience to vulnerability through strategic storage of water through soil moisture storage, artificial reservoirs, and groundwater. There is a huge potential if water storage is addressed in the continuum of the scale from soil water storage to large-scale reservoir storage commensurate to the relevant factors of topography, climate, hydrology, and soils. Ethiopia is a country with the a water storage availability of 43 m^3 per capita in contrast to 750 m^3 per capita in South Africa and about 6150 m^3 per capita in the United States. This underscores the necessity of building strategic storage facilities across the region. A paradigm shift toward protection of the community through such insurance schemes for drought and flood damages is a highly recommended option. Other options such as forecasting and early warning system of seasonal extreme hydrological conditions may be integrated in the overall adaptation strategies. This chapter has overviewed the contextual issues of water resources vulnerability and suggested a way forward for policy makers and planners.

5.22.1 Introduction

5.22.1.1 Seasonal and Spatial Asymmetry

The highly populated coastal floodplains of the Bengal Delta have a long history of water-related natural calamities such as droughts, floods, and cyclones. These events have often been followed by waterborne epidemic outbreaks in coastal as well as inland areas. The diarrheal disease outbreaks in the Bengal Delta, such as cholera, rotavirus, and dysentery, show distinct seasonal peaks and spatial signatures in their origin and progression. However, the mechanisms behind these seasonal phenomena, especially the role of regional climatic and hydrologic processes behind the disease outbreaks, are not fully understood.

The Ganges–Brahmaputra–Meghna (GBM) river system, the third largest freshwater flow regime in the world, flows through the Bengal Delta region to the Bay of Bengal (BoB). The system is composed of two of the largest Himalayan rivers, the Ganges and the Brahmaputra, which are subsequently joined by Meghna in Bangladesh. Most of the annual precipitation in this basin region occurs during the four monsoon months, June–September (Chowdhury and Ward 2007). The lowest flows in the Brahmaputra and the Ganges are recorded during January–April and are typically one-tenth and one-twentieth of the average peak flows in respective rivers. Such drastic reductions cause a drop in the hydraulic head of the GBM system and its tributaries, which aids salt-water intrusion from the coast toward the inland freshwater resources (Rahman et al. 2000), which has significant impacts on available water for agriculture and domestic consumption, ecosystem, and public health (Miller et al. 1982; Wahid et al. 2007; Mirza 2011). The lower parts of the Bengal Delta, especially southwestern Bangladesh, are affected more during this season, when cholera outbreaks are seen in the southern coastal districts (Alam et al. 2006; Akanda et al. 2011) (Figure 1).

The rivers rise rapidly as monsoon rainfall arrives in June (Ahmed and Karmakar 1993) and reach peak flow levels during August–September (Mirza 2011). The entire country is situated on low-elevation alluvial floodplains and prone to flooding by the GBM system at its peak level. About 20% land area of Bangladesh is annually inundated on average; more than 60% in high flood years (Chowdhury and Ward 2007). However, majority flooding takes place in the central and eastern floodplains of Bangladesh. Open mixing of water between sewers, exposed drains, reservoirs, and rivers during floods quickly contaminates the submerged areas with infectious pathogens from other infected water sources. Islam et al. (2006) identified that 62.5% of water samples were infected with the cholera bacteria in suburban reservoirs of Dhaka during the 2004 floods. Water levels on adjoining low-level flood plains may stay inundated till November because of low gradients and congested drainage and serve as ideal habitats for harmful vibrios such as *Vibrio cholerae* even after the flood recedes and act as sources of infection for the surrounding population (Schwartz et al. 2006).

5.22.1.2 Spatiotemporal Characteristics of Cholera Incidence

Cholera, an acute infectious diarrheal disease caused by the bacterium *V. cholerae*, has reemerged as a global public health issue in recent decades. The world has seen an unprecedented rise in cholera infection and transmission since the 1990s, with recent outbreaks across three continents, in Pakistan, Nigeria, and Haiti (Akanda et al. 2012). Cholera records typically show single annual peaks in most affected areas, such as parts of Africa, Southeast Asia, and Latin America (Hashizume et al. 2008). However, the GBM delta region of the Indian

http://dx.doi.org/10.1016/B978-0-12-384703-4.00520-7

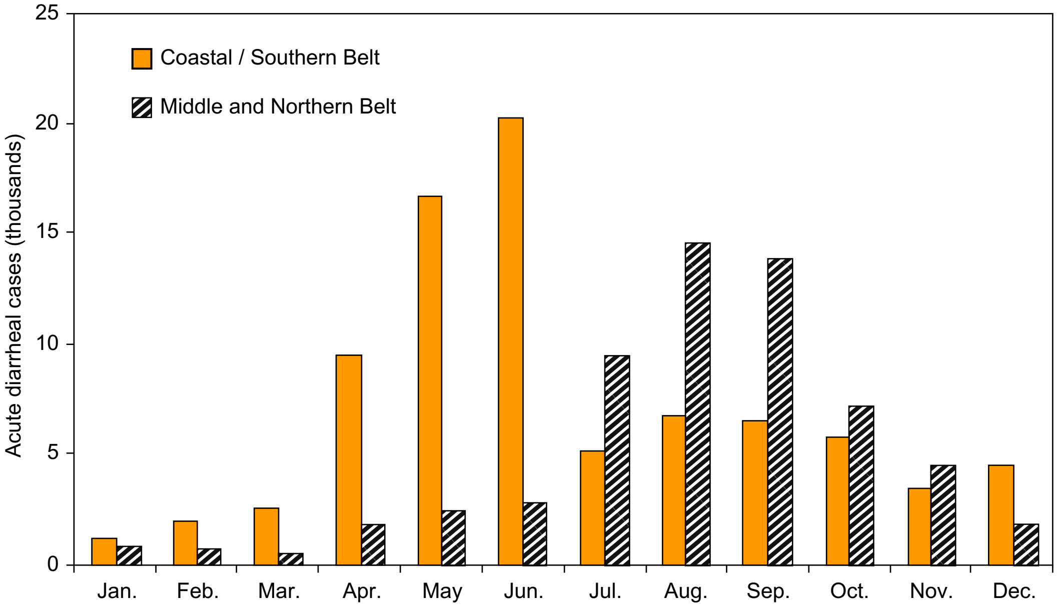

Figure 1 Average monthly acute diarrheal infection observed in the southern (coastal) and northern (middle/inland) areas of Bangladesh, 1995–2000. Source: Akanda, A.S., Jutla, A.S., Alam, M., Constantin de Magny, G.C., Siddique, A.K., Sack, R.B., et al. 2011: Hydroclimatic influences on seasonal and spatial cholera transmission cycles: implications for public health intervention in Bengal Delta. *Water Resour Res.*, 47, W00H07, doi: 10.1029/2010WR009914.

subcontinent shows distinct biannual peaks in central floodplain regions, spring peaks in coastal areas, and fall peaks in inland floodplains (Sack et al. 2003; Akanda et al. 2011). A coupled analysis of the regional climatic processes and cholera surveillance data reveals a strong association of the significant outbreaks with seasonal climatic processes and extreme events. In addition, evidence suggests that cholera outbreaks are propagated from coastal to inland areas and from spring to fall influenced by two distinct, pre- and postmonsoon, hydroclimatic processes (Akanda et al. 2011).

The cholera surveillance program at the International Center for Diarrheal Disease Research, Bangladesh (ICDDR,B) provides some of the longest and largest records available in the world (Longini et al. 2002). The program carries out systematic subsampling of all patients visiting the hospital through laboratory tests to confirm *V. cholerae* infection. The cholera incidence patterns in the Bengal Delta region exhibits significant seasonal and interannual variability, revealing the association of the spring cholera outbreaks with the low flow season of the GBM rivers. Cholera incidence decreases during peak monsoon months (June–September) but starts increasing again in later monsoon, with a larger second peak in October and November (Schwartz et al. 2006). More spring outbreaks are typically seen in coastal districts, whereas fall outbreaks are typically seen in central and northeastern Bangladesh (Akanda et al. 2011). For example, Mathbaria, a coastal area near the coast of BoB experiences cholera outbreak peaks only during March–May, whereas Chhatak in the northeastern corner of the country typically observes late fall peaks (Figure 2).

Cholera epidemics in Bangladesh have been previously linked to a range of climatic and environmental variables such as sea surface temperature (SST) and sea surface height (SSH) (Lobitz et al. 2000), plankton abundance (de Magny et al. 2008; Emch et al. 2008), precipitation (Hashizume et al. 2008), floods (Koelle et al. 2005), peak river level (Schwartz et al. 2006; Emch et al. 2008), salinity (Miller et al. 1982), and fecal contamination (Islam et al. 2006). However, most of the above-mentioned studies tried to explain the dual-peak outbreaks with single-peak environmental variables, and thus the relationships between underlying hydroclimatic and environmental processes and biannual cholera incidences in Bangladesh, and also the asymmetry in spatial distribution of cholera outbreaks are not understood well. More specifically, how these large-scale processes initiate or propagate cholera outbreaks in different areas of the Bengal Delta and how the seasonal and interannual variability of cholera incidence show distinct spatial signatures at different hydrologic regimes are not known. The following sections in this chapter will attempt to identify the key hydrologic, climatic, and environmental processes that are known to play crucial roles in cholera transmission and provide a detailed understanding of the role of the hydroclimatic extremes and resulting population vulnerability to cholera outbreaks.

5.22.2 Key Hydroclimatic and Environmental Processes

5.22.2.1 The Concept of Seasonal and Spatial Transmission Cycles

Cholera broke out as part of a global pandemic in the Bengal Delta region of the Indian Subcontinent during the early nineteenth century (Sack et al. 2004). About 200 years later, the disease still remains a major threat to public health in the

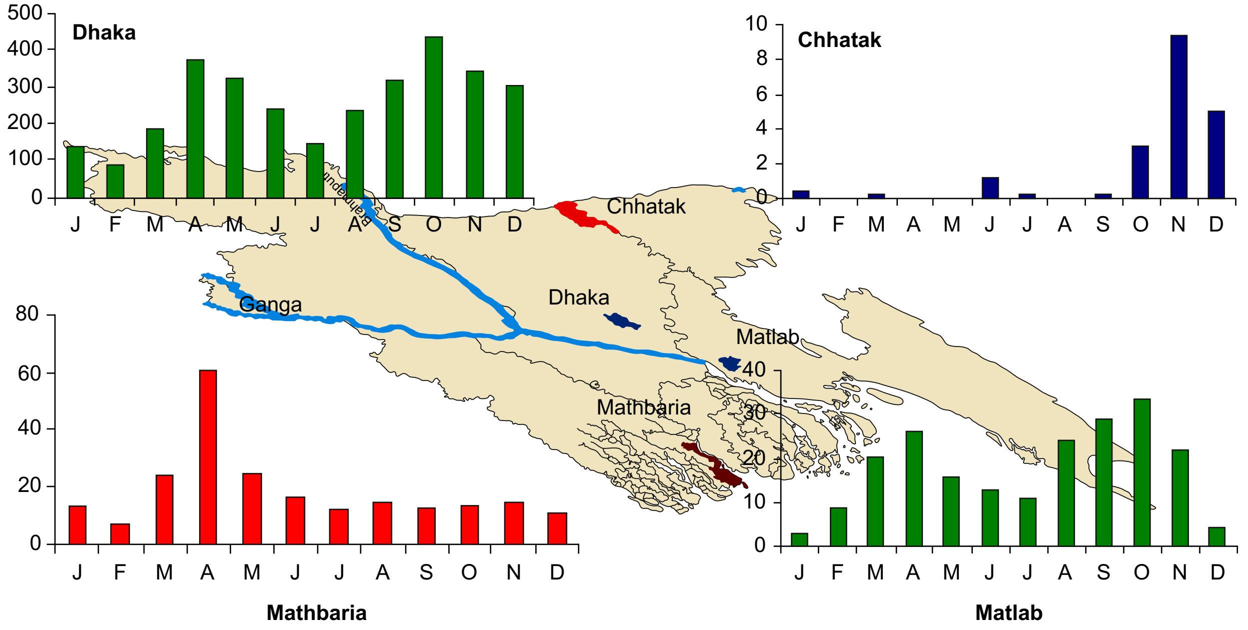

Figure 2 Monthly climatology of cholera incidence recorded at ICDDR,B surveillance centers in Dhaka, Mathbaria, Chhatak, and Matlab, Bangladesh. Source: Akanda, A.S., Jutla, A.S., Alam, M., Constantin de Magny, G.C., Siddique, A.K., Sack, R.B., et al. 2011: Hydroclimatic influences on seasonal and spatial cholera transmission cycles: implications for public health intervention in Bengal Delta. *Water Resour Res.*, 47, W00H07, doi: 10.1029/2010WR009914.

developing world. Cholera is an acute waterborne diarrheal illness caused by two toxigenic strains of the bacterium *V. cholerae*, O1 and O139, which are associated with marine plankton species (Colwell and Huq 2001). There is agreement on the coastal nature of early outbreaks of this infectious disease however, the striking seasonality and strong interannual variability as well as its annual recurrence and spatial variability in endemic areas remain a mystery to scientists and public health professionals Jutla et al. 2010).

For the past several decades, cholera research has primarily focused on clinical, microbiological, and ecological aspects of the bacterium, including vaccines, therapy, and improved treatment. The role of underlying hydrologic, climatic, and other large-scale environmental processes in transporting cholera bacteria through the ecosystem and propagating the disease in different seasons has received less attention (Jutla et al. 2010). Earlier studies related to cholera outbreaks in Bengal have mostly focused on rural areas (Cockburn and Casanos, 1960; Glass et al. 1982; Bouma and Pascual 2001). In fact, an overwhelming fraction of the investigations on cholera outbreaks (Longini et al. 2002; Ruiz-Moreno et al. 2010) and the role of environmental factors (Koelle et al. 2005; Emch et al. 2008; de Magny et al. 2008) have relied on surveillance data from Matlab. Also, these studies did not attempt to explain how large-scale drivers (e.g., precipitation, flood, temperature) with single annual peaks create dual seasonal peaks in cholera incidence.

Siddique et al. (1994) was perhaps the first study to suggest plausible pathways of the progression of cholera outbreaks from the coastal regions of Bangladesh to the inland areas of the country during major epidemics. A more recent study, by Sack et al. (2003), showed that spring peaks are more common in locations closer to the coast, whereas the inland locations are affected mostly by fall outbreaks. Taken together, these studies suggest a spatial heterogeneity of cholera outbreaks across the Bengal Delta region. Akanda et al. (2011) showed that same-year seasonal cholera outbreaks are also strongly correlated, but the seasonal correlation broke down between successive years between 1980 and 2007. An intriguing finding of this analysis is that summer and fall prevalence are dependent on preceding spring outbreaks; however, fall outbreaks do not have an impact on subsequent spring prevalence, suggesting a break in transmission during winter.

Jutla et al. (2010) previously argued that coastal plankton abundance in the BoB and the associated saltwater and vibrio intrusion during the dry season (January–April) may initiate early cholera outbreaks in the GBM Basin. On the other hand, as the streamflow direction is predominantly southward in regional rivers during and after the monsoon season (June–November) (Mirza 2011), there would be no realistic way for coastal plankton to reach estuarine rivers during these months. If coastal plankton abundance, salinity, and associated bacteria affect inland water resources only during spring, and if summer and fall prevalence are dependent on the preceding spring outbreaks, one would expect to see a physically consistent pattern of prevalence in regions affected by coastal intrusion.

Figure 1 shows the monthly average number of cholera cases recorded at each of these four locations. The spatial and temporal patterns of cholera incidence suggests that coastal hydroclimatic processes primarily modulate the first outbreak season in spring, whereas inland processes exhibit a strong influence on the second cycle of outbreaks. Mathbaria, a coastal location close to the BoB, shows cholera outbreaks during the dry season, whereas Chhatak shows outbreaks only during the fall months following the monsoon season. Dhaka and Matlab, located in the floodplain corridors of the GBM rivers, are affected by both outbreaks.

Another interesting observation of the above-mentioned studies is that monsoon rainfall in the region also shows a consistently positive relationship with summer and fall cholera prevalence (Akanda et al. 2011). As streamflow is an aggregated measure of rainfall, it is expected that precipitation would exhibit a positive influence similar to that of streamflow (Akanda et al. 2009). However, as the arrival, duration, and intensity of monsoon rainfall, as well as the terrain and topography, can widely vary over the 1.5-million-km^2 GBM Basin (Chowdhury and Ward 2007; Ahmed and Karmakar 1993), and as the vast majority of water arrives from upstream regions (Mirza 2003), the role of monsoon rainfall in the contamination of water resources inside Bangladesh may actually be limited compared to that of large-scale flooding in the GBM Basin region due to flow from upstream. This assertion is also validated by the observed stronger relationships between fall cholera prevalence and available flood affected area (FAA) statistics in Bangladesh (1980–2007) (Akanda et al. 2011). Another important observation from the aforementioned studies is the consistent asymmetric influence of dry- and wet-season processes on same-year spring and fall cholera outbreaks, respectively: negative correlation in spring and positive values in fall. Winter SST in coastal BoB, dry-season rainfall in Bangladesh, and low flow values in GBM rivers all show strong negative influences on spring cholera prevalence; these variables show consistent negative correlation values over subsequent summer and fall seasons, suggesting that freshwater scarcity in upstream rivers and resulting saltwater and plankton intrusion, as well as the environmental changes during the dry season may affect the cholera outbreaks in all the subsequent seasons of the year.

5.22.2.2 Dual-Peak Cholera Dynamics and Impact of Large-Scale Climatic Extremes

The El Niño-Southern Oscillation (ENSO) phenomenon is considered a primary modulator of global climatic events (Ropelewski and Halpert 1986). For example, studies have investigated the relationships between ENSO and streamflow for large tropical rivers such as the Nile and the Congo (Amarasekera et al. 1997; Molinier et al. 2009) and the Ganges (Whitaker et al. 2001). ENSO-related variability has been used to forecast streamflow (Piechota and Dracup 1999; Hamlet and Lettenmaier 1999; Whitaker et al. 2001) and precipitation patterns in the Asian monsoon (Lim and Kim 2007). The ENSO is also known to influence the occurrences of various infectious diseases in many parts of the world (Patz 2002; Harvell et al. 2002). Studies have suggested relationships between the ENSO cycle and cholera epidemics in Peru (Salazar-Lindo et al. 2008; Martinez-Urtaza et al. 2008) and Bangladesh (Koelle et al. 2005; Pascual et al. 2000; Rodo et al. 2002). Studies of large-scale climate effects on infectious disease, including cholera, are limited and have primarily focused on the effects of ENSO in South Asia and Peru (Martinez-Urtaza et al. 2008; Pascual et al. 2000; Rodo et al. 2002).

Extreme climatic events such as prolonged droughts, floods, and major cyclones can cause major cholera and other waterborne epidemics; such extreme events are also likely to create unseen changes in the ecosystem and introduce new biotypes of the harmful pathogens (Siddique et al. 1994, 2010). Studies over the past three decades provided valuable information on the temporal patterns of cholera outbreaks and relationships with ENSO (Rodo et al. 2002; Pascual et al. 2008). However, relationships with cholera and other major diarrheal diseases show limited understanding of the underlying physical processes governing disease transmission.

For example, Pascual et al. (2000, 2008) and Rodo et al. (2002) suggested long-range teleconnections between ENSO and Bengal cholera but did not elaborate on how the warm or cold phase of ENSO would have different impacts on individual seasonal outbreaks. While the Ganges basin part of the region has shown increased flow with the La Niña phase (Whitaker et al. 2001), the higher share of discharge seen in the Brahmaputra Basin has no known influence because of the phenomenon (Jian et al. 2009). As the rivers are known to have a strong contrasting affect on the cholera dynamics in the two outbreak seasons in this region (Akanda et al. 2009), the role of ENSO needs to be interpreted in the context of the seasonal role of individual rivers, not as a teleconnection having a unified affect. Also, Koelle et al. (2005) and Pascual et al. (2008) reported an 11-month lag relationship between ENSO indices and cholera dynamics in Bangladesh; as well as a 14-month lag between rainfall in India and subsequent outbreaks in downstream Bangladesh. However, questions remain on how the warm (El-Niño) and cold (La-Niña) phases of the phenomenon may affect the discharge characteristics of the major rivers in this region differently and how such a large-scale phenomena would affect cholera outbreaks in Bangladesh in two different seasons.

In addition, the occurrences of floods in these rivers have been found to be modulated by separate mechanisms, leading to devastating floods when streamflow peaks coincide (Mirza 2003). Thus, instead of analyzing the ENSO teleconnections as unified influences, the effects on streamflow and precipitation characteristics in each river basin should be investigated separately. In addition to ENSO, long-term records of the global climatic phenomena such as the Indian Ocean Dipole (IOD) (Saji et al., 1999) and Pacific North America (PNA) oscillation (Peings et al., 2009) need to be studied to identify the impacts on the dry- and wet-season hydroclimatologies in the region and the changes in climatic variables relevant to cholera.

Jutla et al. (2010) reports how the coastal environmental and hydroclimatic processes can modulate cholera dynamics in coastal Bangladesh. SST changes in the BoB region can influence the cholera transmission patterns in spring, through changes in the coastal production characteristics (Jutla et al. 2011), and also in fall, through link region's monsoon precipitation characteristics. Akanda et al. (2009) show that the probability of elevated spring cholera outbreaks is the highest in the strongest drought years and the least during the weakest drought years. The probability of a spring cholera outbreak to exceed a certain threshold of incidence rates is always significantly higher in a water scarce year than in a water abundant year. Conversely, the probability of a large cholera outbreak in fall is found to be distinctively higher for high flood years, although the probability in a lower-than-average flood year was indistinguishable from that of an average flood year in the Bengal Delta.

Akanda et al. (2011) showed that the years showing the highest cholera burden all began with low discharge and thus high saline conditions, thus reinforcing the role of coastal processes in spring. In a drought year, if freshwater flow from upstream regions is anomalously lower during the dry season, the resulting increased coastal salinity extent is expected to expose a bigger segment of the population living in the coastal belt to an environment conducive to vibrio growth and subsequently increased risk of cholera transmission in spring. A scenario opposite to the above scenario is a weak drought year, with anomalously high flow in the GBM rivers during the dry season, when we see lower salinity and limited vibrio growth in estuarine areas and subsequently, lower manifestations of spring cholera incidence. For the later parts of the year, anomalously higher monsoon flow leads to flood inundation across the lower Bengal Delta and an elevated risk of cholera infection. Increased levels of local precipitation and lack of flood drainage can further endanger urban population centers located in floodplains across Bangladesh.

5.22.3 Hydroclimatology and Associated Population Vulnerability

5.22.3.1 Hydroclimatic Variability in the Bengal Delta

The frequency and intensity of hydrologic extremes could increase over many areas during the twenty-first century according to the IPCC projections (IPCC, 2011). Such changes in hydrologic extremes and resulting environmental conditions would likely lengthen the transmission seasons of important water borne diseases and alter their geographic range as well as seasonality (Harvell et al. 2002; Colwell 1996). Studies have shown association between extreme rainfall events and outbreaks of waterborne diseases (Hashizume et al. 2008; Cash et al. 2008). Most of these health effects are likely to occur where hydrologic, climatic, and ecological extremes converge with population vulnerability. Extreme climatic events such as prolonged droughts, floods, or cyclones may increase in the GBM region, which may cause major waterborne epidemics and introduce new biotypes of the bacteria (Siddique et al. 1994).

Seasonal cholera transmission cycles (previous section) also need to be viewed in the context of hydroclimatic variability and observed changes in the region. Hydrological observations over past decades indicate that the annual average runoff in some subtropical and lower midlatitude regions have decreased, while there are forecasts of an increase in high latitudes and parts of the tropics in the coming decades (Milly et al. 2005). It is important to understand that the possible effects of such changes on the transmission of waterborne diseases are likely to be distinctly different in dry and wet seasons. For example, the longer and warmer dry seasons in the Ganges basin region of India (Goswami et al. 2006) are likely to lead to increased water scarcity in downstream Bangladesh. In addition, population and economic growth in the region and diversion in upstream areas are likely to affect water availability and ecosystem health downstream. Lower freshwater flow during the dry season and increased salinity in the GBM estuarine region will also impact safe water and sanitation access at local scales, agricultural activities and crop patterns, and also provide a larger area conducive to bacterial growth and proliferation, subsequently affecting public health in coastal areas (Mirza 2011).

On the other hand, monsoon precipitation variability and resulting runoff changes in the Brahmaputra basin region of South Asia will have further impacts on agricultural productivity, causing loss of lives and property, and on water and sanitation, leading to subsequent water-related disease outbreaks. Goswami et al. (2006) found increasing extreme precipitation events in central India, which covers a large part of the Ganges Basin. One possible outcome of these changes will be devastating floods in eastern and northeast India and downstream GBM floodplains. With the current level of greenhouse gas emissions, by 2080, the number of people flooded annually may increase from 13 million to 94 million in South Asia (Milly et al. 2005). More extreme flood events such as in 1988 or 1998 (Mirza 2011) may occur at shorter intervals and lead to rise in cholera outbreaks and frequent and widespread diarrheal epidemics (Siddique et al. 2011) (Figure 3).

Sea level rise and associated salinity intrusion may also disrupt the estuarine ecosystems and increase riverine salinity extent during the dry season up to that of bigger urban centers (Loucks et al. 2010), providing brackish conditions for increased bacterial growth and subsequent cholera transmission in spring months (Akanda et al. 2011). An important observation of the above analysis is that observed and projected hydroclimatic variability and changes will have detrimental impacts on cholera dynamics in the Bengal Delta region; increased water scarcity in the dry season, higher monsoon rainfall runoff during the wet season, as well as sea level rise and resulting ecosystem changes in southern coastlines. However, increased dry-season discharge and shifting streamflow patterns in the Brahmaputra Basin in the form of higher discharge because of possible warming may provide temporary relief to dry-season scarcity, downstream ecosystem requirements, and overall cholera burden in the downstream GBM region, although the long-term future of such changes and runoff availability in the coming decades remain questionable (Kehrwald et al. 2008; Barnett et al. 2005). Accurate estimation of regional climatic variability and resulting hydrologic and environmental changes will create useful actionable knowledge for water management and public health officials in South Asia for planning and preparing effective adaptation strategies and intervention efforts.

5.22.3.2 Population Vulnerability Over Large Geographic Regions

Previous studies focusing on environmental and climatic drivers of diarrheal disease dynamics have not highlighted the spatiotemporal nature of population vulnerability due to the influence of these large-scale drivers. A large segment of the population in Bengal Delta floodplains remains vulnerable to large-scale waterborne disease transmission mechanisms, influenced by estuarine salinity and inland flood inundation variability, that set the ecological and environmental ‘stage’ for diarrheal outbreaks over large geographic regions. Cholera outbreaks are thus understood to be severely underestimated in the southwestern regions because of increased salinity

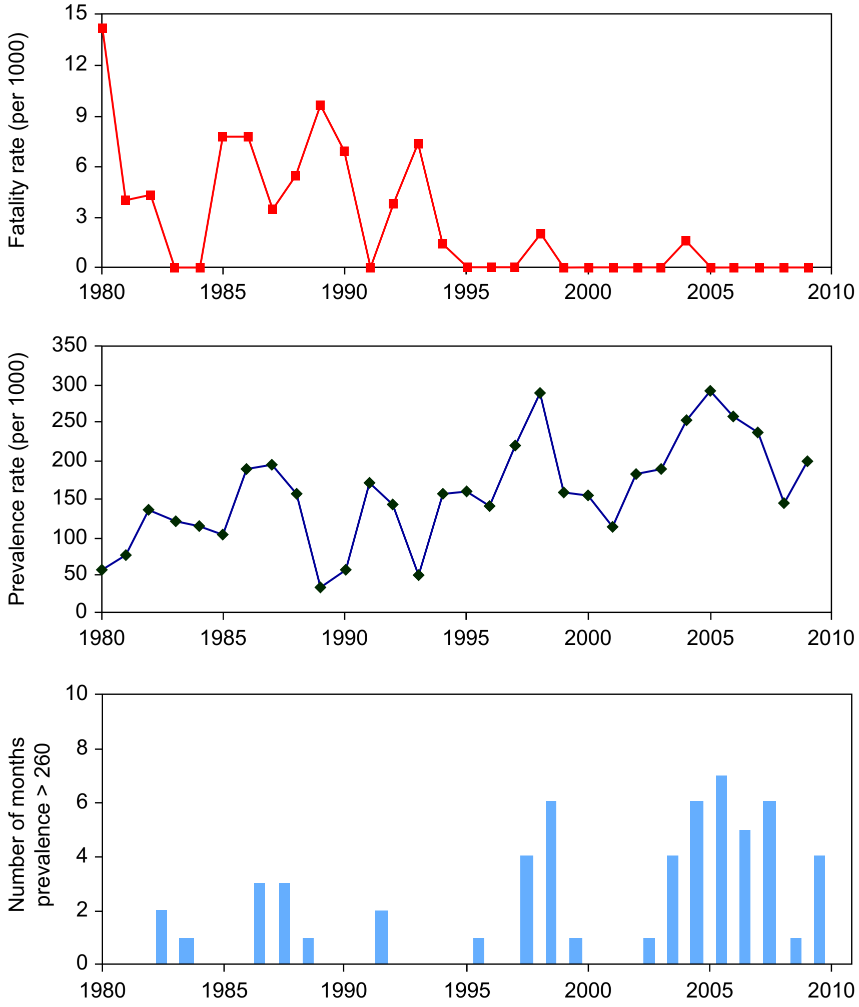

Figure 3 Selected cholera statistics at ICDDR,B (a) Average annual case-fatality ratio in Dhaka (%), (b) average annual prevalence rate for 1980–2009, and (c) number of months with prevalence rate greater than the long-term average 26%.

signatures during spring and because of continuing flood inundation across large areas in fall. An epidemic outbreak in either spring or fall with the concurrent appearance of large-scale climatic extremes such as droughts or floods, respectively, may seriously overburden the public health response system in Bangladesh. A quantitative understanding of the relationships among the hydroclimatological drivers and seasonal diarrheal outbreaks will help early disease detection and prevention efforts. The above linkages can be used to develop 'climate-informed' early warnings and effective means for intervention and preempting epidemic outbreaks in vulnerable regions.

Coastal processes are likely to contribute to spring transmission mechanisms of cholera and other diarrheal diseases, whereas widespread flood inundation and associated physical damage and contamination of water resources seem to dominate disease transmission in fall. To establish the physical role of these seasonal processes in perpetuating the progression of cholera outbreaks from spring to fall, Akanda et al. (2011) performed detailed hydrologic–hydrodynamic simulations over the GBM Basin region in Bangladesh for 20 years (1988–2007) to estimate the nature of salinity intrusion in the dry periods and flood inundation during and after the wet season. Figure 4 shows the spatial distribution of average (MAM: March–April–May months) riverine salinity in southwestern Bangladesh during this period and average flood extent in the wet season (JASO: July–August–September–October months). As seen in Figure 4, population over large geographic sections of Bangladesh remains vulnerable to cholera infection in the spring and fall seasons because of large-scale water contamination and bacterial proliferation in the GBM floodplains in two separate seasonal processes, separately.

In summary, the increased salinity in the estuarine areas during spring provides an optimum environment for growth and increased abundance of *V. cholerae* (Louis et al. 2003; Vital et al. 2007). Inundated lowland areas during and after monsoon floods, on the other hand, provide vast inland areas with standing water and rain-flushed nutrients, providing a growth environment for pathogens (Islam et al. 2006). However, as the above symptoms of transmission mechanisms are typically manifested at a regional scale, other population centers in the floodplains region are also

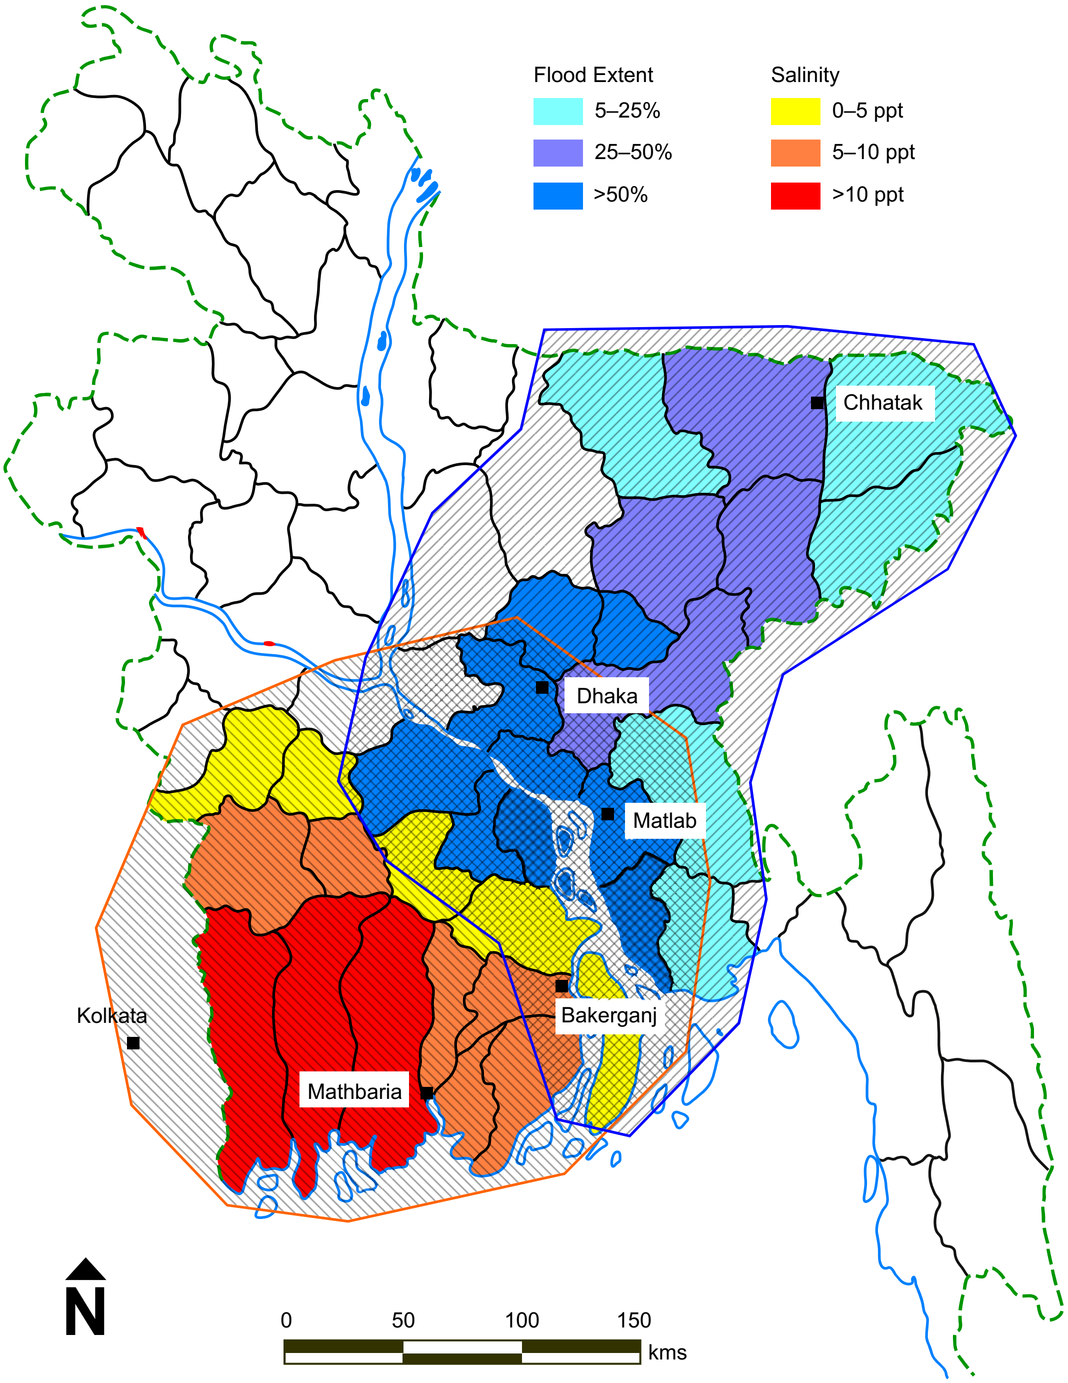

Figure 4 Areas under risk of recurrent cholera outbreaks in spring and fall because of cholera transmission mechanisms driven by coastal salinity intrusion (ppt) (approximate area under influence of the spring transmission mechanism are shown by the orange shaded region) and regional flood inundation (%) (approximate area under influence of the fall transmission mechanism are shown by the blue shaded region) (based on 1988–2007 average).

likely to be vulnerable because of the same mechanisms in the same period. Thus an improved understanding of the macroscale hydroclimatic drivers with accurate estimates of salinity intrusion and flood inundation and their spatial signatures would greatly aid the identification of vulnerable population centers at increased risk of epidemic outbreaks.

5.22.4 Conclusions

5.22.4.1 A Seasonal—Spatial Transmission Paradigm

The combination of a strong seasonal hydroclimatology, high population density, floodplain geography, and coastal ecology has made the Bengal Delta region especially vulnerable to periodic cholera outbreaks. Increasing population and economic development, massive urbanization, and possible changing climate patterns are likely to have significant public health impacts on the region, especially for water-related and waterborne diseases. According to the World Health Organization (WHO) estimates, cholera affects about 3–5 million people annually and about 100,000–150,000 die worldwide each year. The WHO has long supported the development of an early warning system for epidemic cholera outbreaks using climatic and environmental data. Although researchers (Hashizume et al. 2011; Pascual et al. 2008; de Magny et al. 2008) have attempted to predict epidemic cholera outbreaks, an accurate climate-based early warning system is yet to be developed and implemented at an operational level. More importantly, these studies did not sufficiently identify and incorporate the asymmetric and large-scale nature of climatic and environmental influences. The recent findings identify two plausibly important physical variables in the transmission process, estuarine salinity and inland flood inundation, and suggest that seasonal asymmetry and spatial heterogeneity of underlying hydroclimatic processes should be taken into account for developing meaningful predictive models and understanding the scale of population vulnerability to disease transmission mechanisms over large geographic regions.

In this study, we provide a physical understanding based on the regional large-scale environmental and hydroclimatic processes on how the first outbreaks of cholera may be related to low flow discharge of the GBM rivers and subsequent plankton intrusion during spring. Cholera incidence values in this season are inversely related to streamflow volumes, that is, bigger spring cholera peaks are seen in strong drought years. On the other hand, autumn cholera outbreaks are positively correlated to peak streamflow volumes, that is, bigger autumn peaks are seen in high flood years. Evidence points to the breakdown of sanitation and subsequent water contamination, which impacts the population gathered in the few remaining dry areas.

Lack of reliable and continuous cholera incidence data as well as poor coverage in both time and space has traditionally hindered research on understanding the climate–cholera connection. Most published literature on Bengal cholera and climate have only used data from Matlab (e.g., Pascual et al. 2008; Koelle et al. 2005; Cash et al. 2008; Islam et al. 2009), a small coastal town in Bangladesh, and consequently, provided a potentially skewed and incomplete understanding of transmission and propagation of cholera in the Bengal Delta region.

Recent findings indicate that *V. cholerae* outbreaks can be highly local, occurring simultaneously in various locations possessing favorable environmental conditions (Stine et al. 2008; Alam et al. 2011). Thus, the likelihood of an epidemic cholera outbreak in Dhaka because of an extreme hydroclimatic event, such as a drought or a flood, means that major population centers along the floodplains are also concurrently vulnerable (Akanda et al. 2011). The results also suggest that with such an understanding of the underlying large-scale drivers, there is potential to predict the timing and magnitude of cholera outbreaks.

The presented analyses indicate that estuarine salinity and inland flood inundation can significantly affect cholera transmission in the Bengal Delta region. In addition, our analyses show that large areas of the highly populated floodplains in this region remain at high risk of epidemic outbreaks in spring and fall because of the large spatial coverage of salinity intrusion and flood inundation, respectively. Population centers along the floodplain corridors of the GBM river system such as Dhaka and Matlab remain vulnerable to such cholera transmission mechanisms in both the spring and fall seasons (Figure 4). The physical basis of this argument is that the highly asymmetric hydrology of the GBM region leads to a drastic reduction of streamflow from upstream regions in the dry season and a significant drop in the hydraulic head, accelerating the salinity intrusion from BoB toward inland freshwater (Rahman et al. 2000). This inward movement of seawater may help transport *V. cholerae* from coastal areas, and the increased salinity of the estuarine rivers also provides a larger optimal growth environment for the bacterium.

Another important finding of this study is that GBM cholera outbreaks are propagated from the spring to fall seasons and from the coastal to inland regions because of the physical nature of underlying hydroclimatic drivers. Schwartz et al. (2006) reported that *V. cholerae* strains isolated during peak monsoon months are identical to the strains detected in subsequent fall outbreaks, and this strengthens the hypothesis of a second transmission cycle beginning in summer and continuing into fall. Future research needs to focus on a detailed characterization of estuarine salinity at a community scale, which will be helpful for early identification of population vulnerability and targeted intervention and mitigation of spring outbreaks. Also, maintaining higher dry-season discharge in specific rivers (e.g., through the Gorai, the main distributary of the Ganges into southwestern Bangladesh) may have significant beneficial impacts on public health in later seasons of the year.

5.22.4.2 Policy and Public Health Implications

The previous sections of this chapter discussed how cholera outbreaks in the Bengal Delta region were linked to and modulated by significant hydroclimatic events during the past three decades. The findings can be incorporated into a predictive surveillance capability that would help identify vulnerable population groups in the region at risk of imminent cholera outbreaks depending on salinity or flooding signatures in coastal and inland regions as measured 2–3 months in advance. Such a capability would help save lives not only in the urban settings of Dhaka but also in rural population centers along the floodplains of the major rivers that are affected by the large-scale seasonal and spatial large-scale drivers. A predictive system based on the specific information of salinity intrusion and flood inundation patterns shows the promise of predicting future intensity of disease transmission in coastal and inland areas, respectively, and plausibly provides the public health authorities the specific warning necessary to alert medical personnel and implementing preventive measures ahead of epidemic outbreaks.

Recent findings on the large-scale controls of seasonal cholera dynamics suggest that detailed spatial hydroclimatic and hydrodynamic modeling can provide a much-needed lead time to predict the magnitude and location of cholera outbreaks from weeks up to a few months in advance. Seasonal streamflow patterns, coastal plankton abundance, as well as salinity intrusion and flood inundation signatures can be skillful predictors of cholera incidence for the Bengal Delta region and Sub-Saharan Africa. A macrolevel understanding of diarrheal transmission mechanisms is especially vital in the face of observed changes in weather patterns in many developing countries that are vulnerable to endemic and epidemic cholera outbreaks. Based on the accurate prediction and estimated risk of cholera outbreaks, early warnings can be issued in mass media and propagated through cellular-phone-based networks in remote areas. Such networks have proved extremely successful in coastal areas of Bangladesh in reducing cyclone fatality recently and have great potential to be used for epidemic warnings and in adaptation strategies focusing on climate impacts of public health (Akanda et al. 2012).

Evidence suggests that a well-implemented water, sanitation, and hygiene (WASH) infrastructure can significantly reduce diarrheal disease prevalence (Bartram and Cairncross 2010). Such improvements usually require considerable time and resources; however, targeted implementation of WASH in vulnerable localities is feasible and has been highly effective. Large-scale changes in freshwater availability and distribution can severely affect water and sanitation access and public health at the local scale (Howard et al. 2010) and subsequently affect the ability to reach the Millennium Development Goals for most developing countries (Veneman, 2006). A large-scale approach of understanding diarrheal disease mechanisms can also help public health officials make WASH projects more efficient based on early warnings and administer targeted intervention in vulnerable regions. Cholera disease burden can be reduced by predicting impending outbreaks with an actionable lead time of a month to several months and mobilizing experts (physicians and public health workers) and material resources (water purification and sanitation equipment, vaccines, and ORS) to target areas (Akanda et al. 2012).

A climate-based understanding and knowledge of environmental and hydroclimatic drivers can provide a critical time window ahead of impending epidemic cholera outbreaks and enhance the efficacy of existing intervention methods. The combined impact of the proactive and preventive intervention strategies would help reduce the enormous disease burden in the developing world. The role of large-scale hydroclimatic variability in water-related disease transmission is thus a critical component of the climate-water-health nexus and should be incorporated into climate mitigation and adaptation strategies geared toward public health.

5.23.1 Introduction

The humid tropics are generally resource-rich lands. They possess adequate water supply, naturally fertile soils, and a favorable terrain. The morphology of these areas ranges from flat lowland delta to river valleys associated with gently rolling uplands. Most of the major deltas in the world (e.g., Ganges, Mississippi, Niger, Okavango, and Mekong deltas) host large population centers, megacities, complex irrigation systems, and a water-sensitive ecosystem because of their easy access to abundant fresh water and fertile soils. Humid deltas of developing nations support extensive agricultural production. Flooding (extreme and normal) is recurrent in these humid deltas. Floods promote as well as hamper agricultural productivity (depending on the magnitude and spatial extent). Therefore, the socioeconomic fabric of the rural areas of humid deltas in developing nations is intricately related to recurrent flooding, agricultural productivity, and crop loss pattern.

Qualitatively it is easily understood that above-average flooding in these areas may potentially initiate a three-step chain reaction with socioeconomic implications as follows: step (1) floods damage crops; step (2) crop damage results in income loss (seasonal loss of income for farmers); step (3) income loss results in migration (generally toward urban areas). Understanding this three-step chain reaction by quantitative approximation is very important to understanding the observed space–time trends in temporary migration and loss of income for farmers due to recurrent flooding in humid deltas, especially from a climate perspective.

Traditional climate adaptation strategy is usually based on Intergovernmental Panel on Climate Change (IPCC) types of projections (available for various emission scenarios), which is usually predicted by the atmospheric–ocean general circulation models (GCMs) at relatively coarser resolution (Solomon et al. 2007). The adaptation strategy uses the IPCC scenarios without incorporating nonlinearities and interdependencies among resources following a top-down approach and thereby involves uncertainties and could be very risky to adapt (e.g., MoEF 2008). Researchers also increasingly recognize the challenge of skillful forecasts of future global and regional climate due to the diverse types of global and regional radiative and nonradiative climate forcings (Pielke 2001). None of the existing global climate models include all of the important forcings and feedbacks (Pielke et al. 2004). Kabat et al. (2004) proposed a new vulnerability paradigm to address the limitations of using global model projections as the primary basis to determine the potential impacts of future climate variations. This vulnerability paradigm, as applied to the Earth system, is a more inclusive approach than prediction. Key vulnerabilities include risks, for example, to regional and global food, water, and energy supplies (Pielke et al. 2004). Sarewitz et al. (2000) suggested that an approach of first assessing key societal and environmental vulnerabilities and then seeking to determine if skillful predictions are possible can accommodate the uncertainties involved in GCM-based, top-down climate adaptation strategies. According to Pielke et al. (2004) and Pielke et al. (2011), the framework for vulnerability assessments should be place-based and have a bottom-up perspective, in contrast to the GCM-focused top-down approach from a global perspective. The vulnerability focus should be on the resource of interest. This chapter addresses the determination of space–time trends in temporary migration and loss of income for farmers due to recurrent flooding from a bottom-up assessment approach. Such an approach can greatly benefit the climate vulnerability assessment and adaptation strategy for humid deltas in developing nations because of its highly contextual nature.

Satellite remote sensing has been used to study crop patterns (e.g., Moran et al. 1997), estimating crop damage (e.g., Okamoto et al. 1998; Silleos et al. 2002) and detection of flood inundation extent (e.g., Smith 1997; Horritt et al. 2001;

http://dx.doi.org/10.1016/B978-0-12-384703-4.00536-0

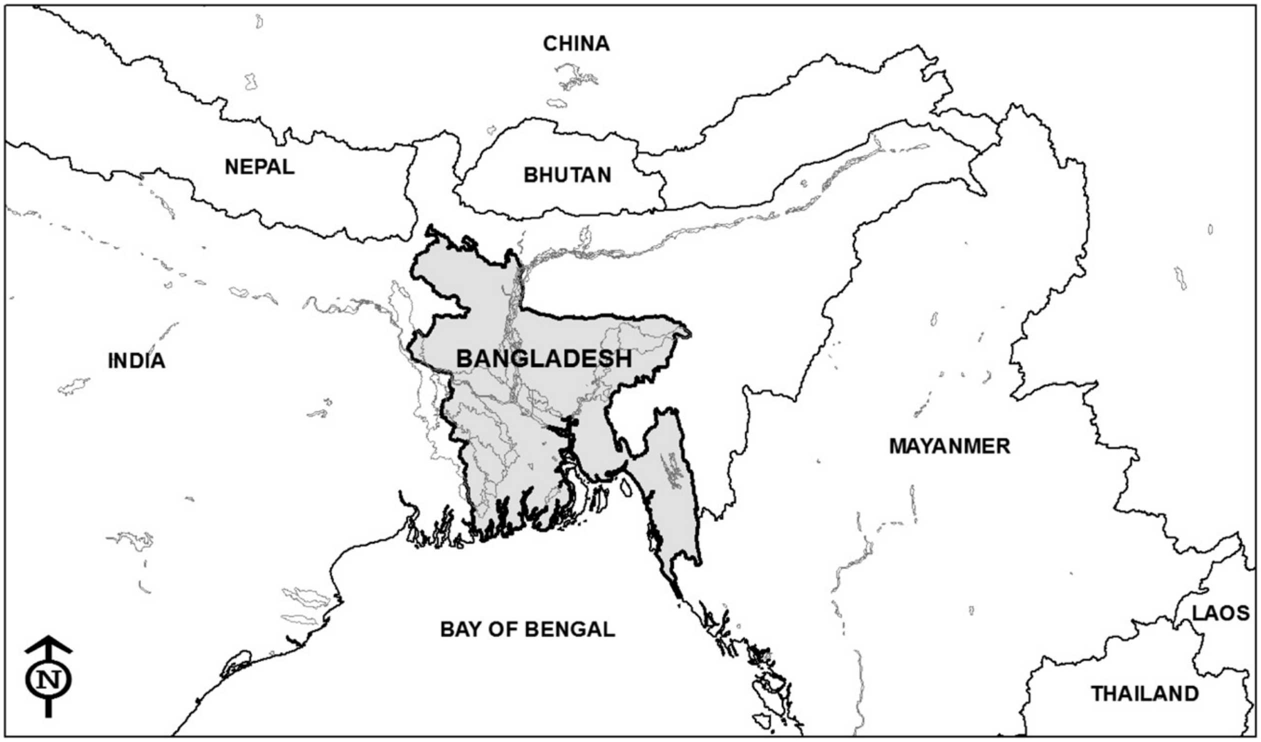

Figure 1 Regional setup of Ganges–Brahmaputra delta (Bangladesh).

Henry et al. 2006) for many years. Hydrologic remote sensing from satellite platforms (NASA products on precipitation, water extent, and water level) also has a proven track record of use for transboundary flow forecasting/prediction. Therefore, because of easy availability and the vantage of space offering a more comprehensive view of a region, satellite data naturally lends itself to routine and affordable monitoring of flooding and crop damage for policy planners at the administrative level. However, no comprehensive research has been conducted to investigate: (1) if satellite remote-sensing data that is used for detection of flooding and crop damage patterns is a reliable and routine proxy for use in socioeconomic models to assess loss of income and migration patterns; and (2) if it is found that remote sensing is reliable as a proxy for migration patterns at planning timescales, what is the 'tipping point' crop damage extent that causes disruptive environmental–economic migration? This chapter provides a summary of the state of the art of remotely sensed data and digital image processing techniques for the successful completion of such a comprehensive research.

This chapter briefly presents the climate vulnerability scenarios of Bangladesh by the bottom-up approach; discusses potential methods and techniques to study the observed space–time trends in temporary migration and loss of income for farmers due to recurrent flooding in humid deltas as a case study in Bangladesh; and reports the existing knowledge base to support each component of the potential methods and techniques described in the first section. The chapter also reports the gaps in the existing knowledge base and recommends potential scope of research to support the remote-sensing-based migration study.

5.23.2 Case Study Site: Bangladesh

Bangladesh (Ganges–Brahmaputra Delta in general—Figure 1) is a representative example of most humid, flood-prone, and heavily populated deltas of Asia and Africa. The availability of much insitu hydrologic data, calibrated models on hydrology and hydraulics, benchmarking of several National Aeronautics and Space Administration (NASA) products and systems, agreements with local agencies, and familiarity with the region are the major factors that influence the decision of the site selection.

Bangladesh is located between 20°and 26° N latitude and 88° and 92° E longitude. It is bordered by India on the west, north, and east; by Myanmar on the southeast, and by the Bay of Bengal on the south. Most of the country is characterized by low-lying land comprising mainly the delta of the Ganges and Brahmaputra rivers. Floodplains occupy about 80% of the country. The mean elevations range from less than 1 m on tidal floodplains; 1–3 m on the main river and estuarine floodplains; and up to 6 m in the northeast (Rashid 1991). Only in the extreme northwest are elevations greater than 30 m above the mean sea level. The hilly areas are occupied in the northeast and southeast portions of the country, with some tertiary hills over 1000 m above mean sea level.

In general, Bangladesh is characterized by a humid, warm, and tropical climate. The climate is influenced primarily by monsoons and partly by pre- and postmonsoon circulations, which mostly originate over the Indian Ocean and carry warm, moist, and unstable air. The onset of the monsoon starts during the first week of June and ends in the first week of October (with some interannual variability in dates). In addition to monsoons, the easterly trade winds are also active in this area, providing warm and relatively drier circulation. There are four prominent seasons in Bangladesh: (1) winter (Dec. to Feb.), (2) premonsoon (Mar. to May), (3) monsoon (Jun. to early Oct.), and (4) postmonsoon (late Oct. to Nov.). Agrawala et al. (2003) described the general characteristics of the seasons in Bangladesh as follows:

1. Winter is relatively cooler and drier. The average temperature range from a minimum of 7.2–12.8 °C to a maximum of 23.9–31.1 °C. The minimum occasionally falls below 5 °C in the north. There is a south to north thermal gradient in winter mean temperature, and generally the southern districts are 5 °C warmer than the northern districts. Frost or snowfall is extremely rare.
2. Premonsoon is hot with an average maximum temperature of 36.7 °C, predominantly in the west for up to 10 days, very high rate of evaporation, and erratic but occasional heavy rainfall from Mar. to Jun. In some places, the temperature occasionally rises up to 40.6 °C or more. The peak of the maximum temperatures is observed in April, the beginning of premonsoon season. In the premonsoon season, the mean temperature gradient is oriented in a southwest to northeast direction, with the warmer zone in the southwest and the cooler zone in the northeast.
3. Monsoon is both hot and humid, and brings heavy torrential rainfall throughout the season. About four-fifth of the mean annual rainfall occurs during monsoon. The mean monsoon temperatures are higher in the western districts compared to those for the eastern districts. Warm conditions generally prevail throughout the season, although cooler days are also observed during and following heavy downpours.
4. Postmonsoon is a short season characterized by withdrawal of rainfall and gradual lowering of nighttime minimum temperatures.

The annual rainfall in Bangladesh ranges from 1200 mm in the extreme west to over 5000 mm in the east and northeast, with a mean annual rainfall of about 2300 mm.

Bangladesh, with an estimated population of about 151.41 million and a population density of about 964 persons per km^2 (BBS 2011) is one of the most populous and densely populated countries in the world (World Bank 2010). The country gained a net population increase of more than 114 million from 1901 to 2011 (BBS 2011). As in some other developing countries, in Bangladesh, the rate of urbanization is extremely high (more than two to three times that of the national population growth rate), being consistently over 5% since 1961, and even up to 20% in some years (Jahan and Rouf 2011) (Table 1). In 1974 people living in urban areas accounted for only 8.8% of the total population. In 2001 the urban population became 23.10% of the total population. The United Nations (UN) estimates that currently about 25% of the people of Bangladesh live in urban areas (Jahan and Rouf 2011).

Migration contributed about 40% to the urban growth in Bangladesh during 1974–81 (Islam 1999). The share was probably similar during 1981–91. For some large cities, this share could even be higher—up to 70%—as in the case of the capital city of Dhaka. The variable contribution of migration to urban growth by cities is evident from Table 2. On the aggregate level, both in- and out-migrations have increased in Bangladesh consistently since 1984 (BBS 1994; Huq-Hussain 1995). The increase is significantly higher in the case of in-migration than of out-migration, indicating robust net migration trends (Figure 2(a)–2(c)).

Table 1 Level of urbanization in Bangladesh (1941–2001)

Census year	*Total national population*	*Total urban population*	*Level of urbanization (%)*
1941	41 997 297.00	1 537 244.00	3.66
1951	42 062 610.00	1 819 773.00	4.33

Adapted from Khan, A. A. M., 1982: Rural urban migration and urbanization in Bangladesh. *Geogr. Rev.*, **72** (4), 79–94.

Dhaka is the largest city in Bangladesh and also the financial, business, and cultural center of the country. The area and population of Dhaka city grew about 58-fold and 35-fold, respectively. Dhaka is also the fastest growing megacity in the world along with Lagos, Nigeria. Dhaka's share of the country's total population has been steadily growing, with a current rate of over 10%. According to UN and World Urbanization Prospects (2009) projection, Dhaka is to move up to the position of fifth-largest megacity with an estimated population of 20.9 million in 2025.

A time series of Landsat-3 Multispectral Scanner System (MSS), Landsat-4/5 Thermatic Mapper (TM), and Landsat-7 Enhanced Thermal Mapper Plus (ETM+) data acquired over Dhaka city were obtained from NASA and the US Geological Survey (USGS) and processed to visually inspect the evidence of high-intensity urban development in Dhaka. Table 3 shows the dates of the acquired Landsat imagery.

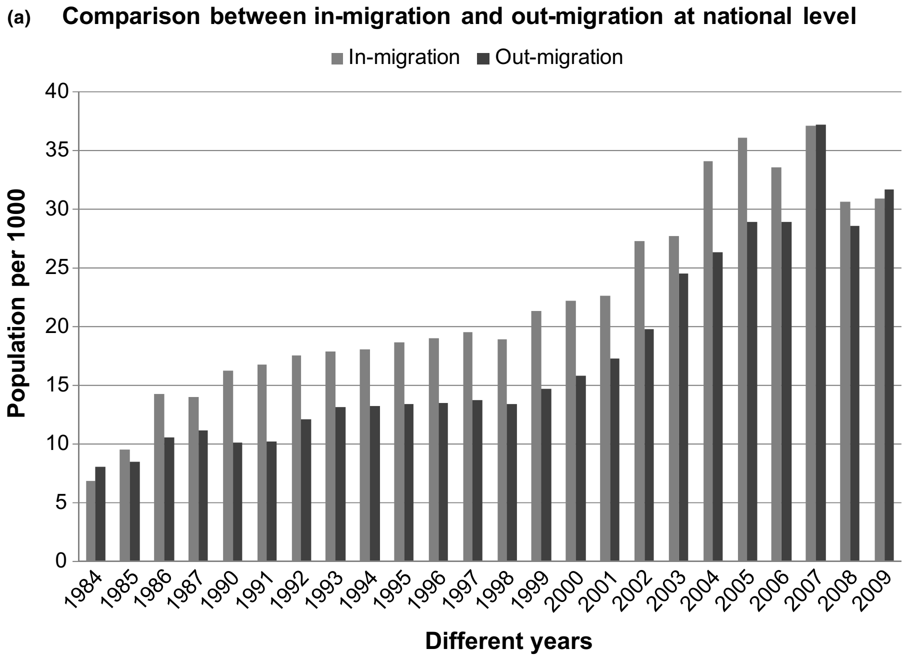
The images were processed, georectified, and displayed with administrative vector layers. The images were displayed as false color composite to emphasize the contrast among vegetation, water, and urban developments. The MSS images were displayed by 1 (red), 3 (green), and 2 (blue) band combinations. The TM and ETM+ images were displayed by 3 (red), 4 (green), and 2 (blue) band combinations. In all cases, vegetated areas are represented by green, and urban areas (mostly impervious surfaces) are represented by light purple. Rivers and other water bodies are represented by black, dark blue, and dark purple colors. Figure 3 shows Dhaka city as captured by the Landsat satellites in 1980, 1989, 2000, and 2003. Figure 4 shows

Dhaka city as captured by the Landsat satellites in 2005, 2006, 2009, and 2010. The time series of these satellite observations clearly shows the major episodes of urban developments in and around Dhaka city.

Most of Dhaka's growth is due to migration from rural areas, especially from the neighboring districts (Figure 5). Due to a disproportionately large concentration of administrative, industrial, educational, and cultural activities, Dhaka city is not only the permanent destination of rural migrants but also attracts hundreds and thousands of daily commuters and circular migrants from neighboring rural districts (Islam 1996).

5.23.3 Climate-Vulnerability Scenarios of Bangladesh by Bottom-Up Approach

Bangladesh is one of the most populous and densely populated countries in the world. It is also one of the poorest countries in



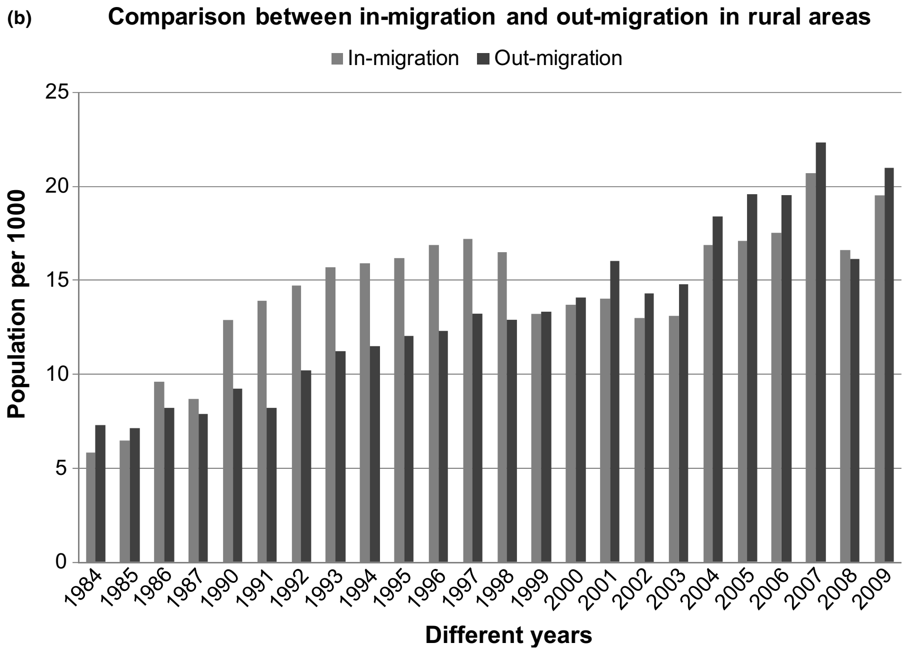


Figure 2 (a) Comparison between in-migration and out-migration rates (1984–2009) at national level. (b) Comparison between in-migration and out-migration rates (1984–2009) in rural areas. the world with a per capita income of $640, which ranks below average South Asian per capita income and per capita income for low-income countries (World Bank 2010). More than one-third (36%) of the people in Bangladesh live in poverty (in rural areas, it is 40%). With the burden of tremendous population growth problem, Bangladesh ranks low on just about all measures of economic development. This low level of development makes the country quite vulnerable to climate, as it combines with a number of hydrogeological and socioeconomic factors such as (1) geographical location in South Asia; (2) flat deltaic topography with very low elevation; (3) extreme climate variability that is governed by monsoon patterns (which results in acute water distribution over space and time); (4) high population density and poverty incidence; and (5) majority of population being dependent on agriculture (about one-quarter of the country's GDP comes from it) (Ahmed 2006).

Although it is difficult to determine Bangladesh's potential to adapt to climate, several key statistics give some insight as to the state of its infrastructure and its social and human capital. In 2000, the World Bank estimated that only 9.5% of the total network (207 500 km) of roads in Bangladesh was paved, which put it well below the average (16.5%) for low-income countries (World Bank 2002), suggesting that its physical infrastructure in general might be less developed than that of low-income countries. In the same year, the World Bank also reported that Bangladesh had only 51 scientists and engineers per million people, a number comparable to that for low-income countries in general. Similarly, gross secondary and tertiary school enrollment stood at 47.5% and 4.8%, respectively, in 2000. A relatively uneducated and illiterate population will be less capable of adapting to climate variations and thus has higher vulnerability.

Several studies, including Agrawala et al. (2003), World Bank (2000), and Huq et al. (1999), discussed the potential impacts of climate on water resources in Bangladesh. Water-related impacts of climate will likely be the most critical for Bangladesh, largely related to coastal and riverine flooding (Agrawala et al. 2003).

Flooding in Bangladesh is a regular feature and has numerous adverse effects, including loss of life, increased frequency of disease, and destruction of property. This is because (1) there are 230 rivers that occupy about 7% of the total land area of Bangladesh, and (2) much of the country is located on a floodplain of three major rivers and their numerous tributaries. The combined basin area of these great river systems is about 1.72 million km^2 and spread over China, India, Nepal, Bhutan, and Bangladesh (Figure 1). Bangladesh is the lowest riparian country with low topography in the basin, and these three major rivers discharge into the Bay of Bengal through the heart of Bangladesh. One-fifth of the country is flooded every year, and in extreme years, two-thirds of the country can be inundated (Mirza 2002). This vulnerability to flooding is exacerbated by the fact that Bangladesh is also

Figure 5 Urban development in Dhaka city due to migration from surrounding districts.

a low-lying deltaic nation exposed to storm surges from the Bay of Bengal.

Severe floods occurred in 1954, 1955, 1970, 1974, 1984, 1987, 1988, 1998, 2004, and 2007. Severe coastal flooding occurred in the years 1822, 1876, 1897, 1942, 1950, 1970, 1974, 1988, 1991, 1994, 1995, and 2007. Based on the historic records, it appears that the frequency, magnitude, and duration of floods have increased substantially during the past few decades. For example, all major floods covering more than 35% of the country occurred after 1974 (Figure 6).

The 1998 flood, one of the worst in recent memory, is an example of how vulnerable Bangladesh is to flooding. The flood was the result of three factors: (1) heavy rainfall and snowmelt in India and Nepal, (2) a 20% increase in rainfall in Bangladesh into its major rivers (the Ganges and

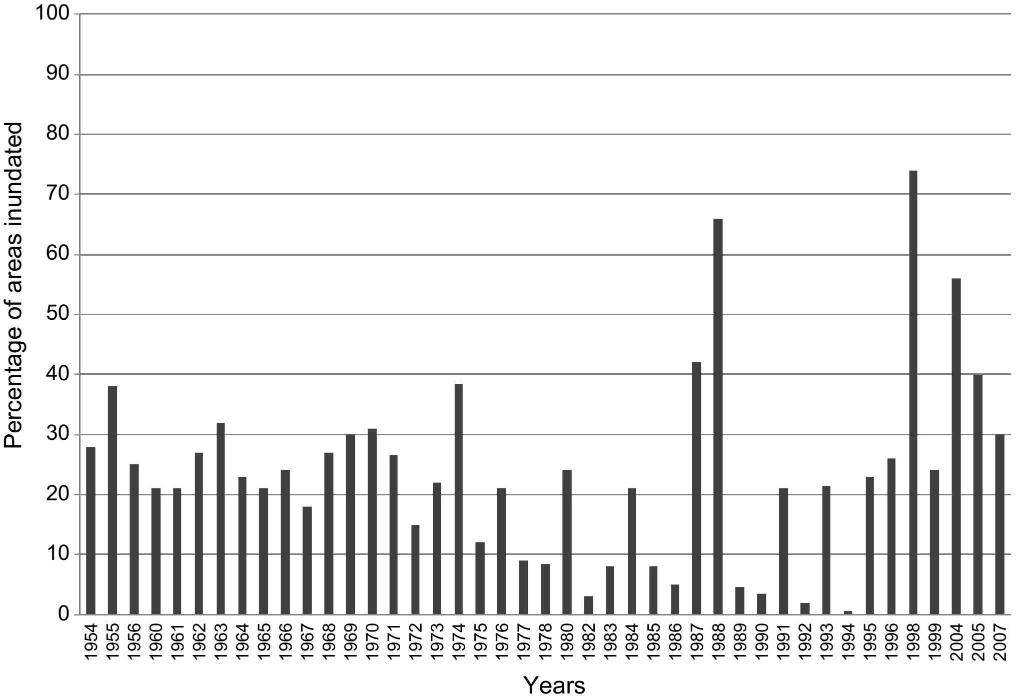

Figure 6 Comparison of flooded areas for different years in Bangladesh. Adapted from Agrawala, S., T. Ota, A. U. Ahmed, J. Smith, and M. Aalst, 2003: *Development and Climate Change in Bangladesh: Focus on Coastal Flooding and the Sunderbans*. Organization for Economic Co-operation and Development (OECD), Paris.

Brahmaputra) and more than double rainfall in the Meghna, and (3) elevated tides in the Bay of Bengal from the monsoon. The third factor did not contribute to runoff, but the elevated tides blocked outflow of the swollen rivers into the Bay of Bengal. The flood inundated close to 100 000 km^2 of land. More than 30 million people were displaced, with 20 million rendered homeless. Hundreds of people were killed directly by the floods, and several hundred thousand cases of diarrhea were confirmed.

There has been a trend in recent decades of much higher interannual variations in flooded areas. As shown in Figure 6, since the late 1970s, flooding events have tended to cover significantly lower or significantly higher areas than had been observed in prior decades. This trend in extremes cannot be simply attributed to climate. Rather several other factors are at play. First, better flood monitoring and control measures have probably contributed to a significant reduction in areal coverage of moderate flooding events, which now cover a much lower area.

Although this is not certain, looking into the future, climate is likely to exacerbate flooding for a number of reasons, including increased glacier melt, increased precipitation, sea level rise, and increased intensities of cyclones, winds, and precipitation.

Higher temperatures will result in more glacial melt, increasing runoff from the neighboring Himalayas into the Ganges and Brahmaputra rivers. Given the altitude of the mountains and the enormous size of the glaciers, this problem will most likely continue over the next century. The problem could be of even greater concern as there is evidence to show that temperatures in the Himalayas (where the glaciers are located) are rising at higher rates, thereby contributing to enhanced snowmelt Mirza and Dixit (1997).

Sea level rise will result in coastal flooding both under ambient conditions (given the low elevations of the coast) and even more so in the event of storm surges. It will also indirectly cause riverine flooding by causing more backing up of the Ganges–Brahmaputra–Meghna rivers along the delta. Assuming a positive correlation between sea surface temperature and tropical cyclone intensity, Ali (1996) calculated the effect of a repeat of the 1991 cyclone with a 2 °C increase (which causes a 10% increase in wind speed) and a 0.3 m sea level rise.

5.23.4 Potential Methods for Remote-Sensing-Based Spatiotemporal Migration Study and Existing Knowledge Base

Analysis of the slum data reported by the Center for Urban Studies (CUS) in Dhaka (in collaboration with the Carolina Population Center at the University of North Carolina in Chapel Hill and the US Agency for International Development, USAID) clearly shows that the continuous increase of the urban slum and squatter settlements has been significantly influenced by the recurrent events of floods. Figure 7 shows the cumulative developments of slum and squatter settlements from the prior years of 1971–2005. Figure 8 shows the association of slum cluster increments with significant flood events. This exploratory analysis indicates that the availability of spatial data for flood inundation, corresponding damage of crops, and migrated settlements can potentially contribute to an

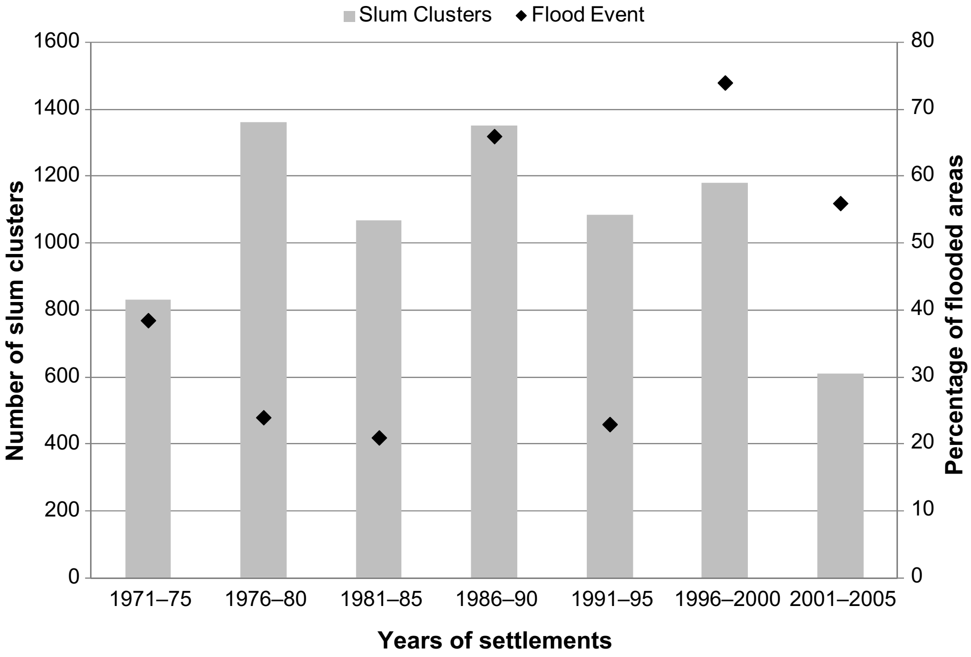

Figure 8 Association of slum cluster increments with significant flood events.

understanding of spatiotemporal migration due to flood. It is strongly believed that the following six tasks can help to accomplish this objective:

Task 1: Preparation of climatologic annual flood inundation maps
Task 2: Validation of satellite-derived inundation maps
Task 3: Multitemporal analysis of flood inundation to detect most flood affected areas
Task 4: Crop damage assessment
Task 5: Preparation of socioeconomic data at the district level
Task 6: Application of socioeconomic models to assess income loss and migration patterns from satellite data

5.23.4.1 Preparation of Climatologic Annual Flood Inundation Maps (Task 1)

This step is to generate a series of flood extent maps for selected years from 1980–2010. The proposed task emphasizes the use of NASA Moderate-Resolution Imaging Spectroradiometer (MODIS) satellite imagery (reflectance data) to create the flood inundation maps after 2000 and Advanced Very High-Resolution Radiometer (AVHRR) imagery before 2000. These maps pertain to the monsoon season (Apr.–Aug.). It is expected to have at least 20 such data sets. Figure 9 summarizes the digital image processing and spatial analysis techniques involved in remote-sensing-based flood extent map generation.

Land cover and land use change (LCLUC) studies were conducted using satellite imagery acquired mainly by Satellite pour l'Observation de la Terre (SPOT), Indian Remote Sensing–1D (IRS-1D), and IKONOS (e.g., Dewan and Yamaguchi 2009) and were focused on specific local areas (e.g., Dhaka district). The LCLUC study of this research should use the satellite imagery acquired by Landsat missions since data acquired by Landsat satellites have extensive temporal and aerial coverage, and they can be obtained from USGS free of cost. Since the devastating floods of 1987 and 1988, there has been significant interest in the country regarding research on floods, especially using geographic information systems (GIS) and remote sensing. Flood inundation extent and flood hazard maps were created for targeted flood events using Radarsat-1 Synthetic Aperture Radar (SAR) and Landsat TM (Hossain et al. 2007; Hoque et al. 2011), MODIS, and Radarsat-1 SAR (Islam et al. 2010), AVHRR (Islam and Sado 2000), and SPOT (Blasco et al. 1992) data. The technique explained in Figure 9 was used to generate a flood extent map for part of Bangladesh using a time series of Radarsat-1 SAR imagery acquired between Jul. 2000 and Oct. 2000. Figure 10 shows the flood extent maps for Jul., Aug., early and late Sep., and Oct. 2000.

5.23.4.2 Validation of Satellite-Derived Inundation Maps (Task 2)

The MODIS- and AVHRR-derived flood extent data can be validated using (1) Radarsat-1 SAR-derived flood extent data and (2) hydrodynamic model-derived flood maps. Shuttle Radar Topography Mission (SRTM) and Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER)-derived digital elevation maps (DEM) can be used in conjunction with water-level data derived from radar altimeter (TOPEX/POSEIDON/Jason-1 and Jason-2/OSTM).

SAR-derived flood imagery is available at the Center for Environmental and Geographic Information Services (CEGIS) (http://www.cegisbd.com) in Bangladesh for selected years for the entire country of Bangladesh and also at district levels. The Institute of Water Modeling (IWM) (http://www.iwmbd.org) in Bangladesh has already simulated floods for the entire country for different events. In addition to IWM's selected data, the year 2002 was simulated using Hydrologic Engineering Centers River Analysis System (HEC RAS) and the Center for Computational Hydroscience and Engineering–Two Dimensions (CCHE2D) flood model (Jia and Wang 1999; Jia et al. 2002) developed at the National Center for Computational Hydroscience and Engineering (NCCHE) (http://www.ncche.olemiss.edu) can also be used. CCHE2D flood simulation results were compared with different satellite-derived flood

maps for the 2008 Midwest USA Flood (Hossain et al. 2009). SRTM- and ASTER-derived DEM can be used in conjunction with water-level data derived from radar altimeter (Siddique-e-akbor et al. 2011).

5.23.4.3 Multitemporal Analysis of Flood Inundation to Detect Most Flood-Affected Areas (Task 3)

The goal of this step is to quantify a given flooding season as 'average,' 'below-average,' or 'above average' in a statistical (percentile) and quantitative (using intensity, duration, and extent of flooding) manner. This classification can be done for each district (equivalent to 'states' – there are 64 districts) because other demographic and socioeconomic data are more reliably available at the district level. Then multitemporal analysis can be performed to detect the areas affected by above-average floods and categorize them based on the frequency of flood visit; in this way, a spatiotemporal matrix of flood frequency can be obtained where pixels are categorized as affected by above-average flood for only a single date, two dates, three dates, four dates, up to all dates. Each district can then be categorized using the flood-frequency matrix results. The districts affected regularly by above-average flood can be selected for crop damage estimation and migration studies. Figure 12 shows the flood duration maps obtained from the multitemporal analysis of the time series of the flood extent maps shown in Figure 10. The technique explained in Figure 11 was used to generate this map.

5.23.4.4 Crop Damage Assessment (Task 4)

CEGIS has conducted a few crop damage assessment exercises (i.e., spatial extent of damaged crops in the postcyclone timeframe), such as after Cyclone Aila, from MODIS data using supervised classification incorporating near-real-time ground evaluation of

the land cover (crop being 'damaged' or 'undamaged'). Hossain et al. (2007) conducted crop damage estimation due to flooding using multitemporal SAR imagery. Figure 13 summarizes the techniques that were used by Hossain et al. (2007).

This technique was applied to map the spatial distribution of the rice crop damage due to the flood that occurred in 2000 (Figure 10). The flood duration and dynamics map for the 2000 flood event (as shown in Figure 12) was used in conjunction with the corresponding crop damage assessment map (as shown in Figure 14), and GIS-based spatial analysis was used to determine the spatial distribution of the damaged crop associated with flood extent and duration. Figure 15 shows the spatial distribution of rice crop damage due to the 2000 flood event in association with flood duration andtrun -1 dynamics. The ground evaluation data acquired by CEGIS can be used in artificial neural network (ANN)-based multisensor data fusion techniques (Pohl and Genderen 1998) using the available optical (Landsat, ASTER, SPOT, and Advanced Land Observing Satellite (ALOS) the Advanced Visible and Near Infrared Radiometer type 2 (AVNIR2)) and microwave (Radarsat-1 and -2 SAR, ENVISAT Advanced Synthetic Aperture Radar (ASAR), ALOS The Phased Array type L-band Synthetic Aperture Radar (PALSAR), and TerraSAR) data over Bangladesh for producing a binary map of 'damaged/undamaged' crops for the areas identified in Task 3 (see Section 5.23.4.3) for each flooding season.

5.23.4.5 Preparation of Socioeconomic Data at the District Level (Task 5)

The socioeconomic data pertaining to migration patterns that is necessary for achieving these research objectives can be obtained from a multilayer archive of Bangladesh government-sponsored

cross-sectional surveys. Through a strategic partnership with the Bangladesh government and United Nations Development Program (UNDP) agencies, the author has acquired and digitized extensive demographic data produced by the Bangladesh Bureau of Statistics (BBS) from labor force and household surveys. In particular, two comprehensive surveys provide multiyear migration data (comprising in- and out-migration) for each of the 64 districts of Bangladesh along with questionnaire input on reasons for migration. The two BBS surveys that were extensively leveraged for this task are:

1. Preliminary report on household income and expenditure survey (2005, 2010), and
2. Report on sample vital registration system–2009. These statistical data were converted into a GIS database to be incorporated in spatial analysis associated with socioeconomic models.

In Bangladesh, the most common forms of settlements for the migrated population are slums and squatters. In Figure 7 it can be seen that the slums and squatter settlements increased almost 10-fold from 1971 to 2005. Figure 8 shows that the major flood events within this period might have significant influence on the increment of the slums and squatter settlements. In 2005, the Center for Urban Studies (CUS), the National Institute of Population Research and Training, and the Monitoring and Evaluation to Assess and Use Results Evaluation (MEASURE) collaborated to physically identify the boundaries of slums and squatter settlements in the six city corporations of Bangladesh. These slum maps were intended to facilitate the implementation of the urban health survey throughout Bangladesh. Information of the spatial distribution of these slums and squatter settlements should be very useful input for the socioeconomic models to assess migration patterns due to income loss. As an attempt to evaluate the potential of this slum data to be used in spatial analysis, the hard copy of the 1996 slum and squatter settlement map (created by CUS) was digitally processed and put into GIS successfully. The GIS data provided the spatial

distribution of slums and squatter settlements for 15 different administrative units of Dhaka Metropolitan City. Figure 16 shows the GIS coverage of the slums and squatter clusters and Figure 17 shows the comparison of areal distribution of these clusters.

5.23.4.6 Application of Socioeconomic Models to Assess Income Loss and Migration Patterns from Satellite Data (Task 6)

In this step, regression relationships (similar to those proposed by Banerjee 2005) can be established. For example, the Banerjee model could be recalibrated and used to predict the loss of rural farmer income from crop damage assessment by remote sensing. Consequently, this loss of income can then be correlated to migration patterns (from the damaged areas to Dhaka city) using protocols outlined in Rayhan and Grote (2007) as well as statistical significance tests. The goal of this step is to identify if frequently available satellite-derived flood-inundation/crop damage assessment can be a reliable proxy for predicting rural-to-urban migration for seasonal and long-term policy and planning. The fitting of equations can be done either in a bootstrapping or cross-validation format or simply using half the data for fitting and the other half for testing predictive accuracy.

5.23.5 Discussion on Potential Scope of Future Research

Potential methods for remote-sensing-based spatiotemporal migration studies and their contributions in contextual vulnerability assessment due to potential climate variability and change with bottom-up perspective (as described by Pielke et al. 2004; Hossain et al. 2011; Pielke et al., 2011) can be summarized by the flow chart shown in Figure 18. The knowledge base achieved with each component of the methods described in the previous section indicates a promising outcome. However, successful completion of each task depends on the availability of good quality data sets and the answers of several open research questions that are discussed as follows.

MODIS has a successful track record of flood inundation mapping. The only issue with the use of MODIS in this regard is having cloud-free imagery. In Bangladesh, during monsoon season it is very difficult to obtain cloud-free imagery. A number of researchers have addressed this problem and proposed several methods to restore the data covered by cloud (Ren et al. 2009a,b). It is believed that adaptation of these methods along with further research could be useful to ensure the use of MODIS data for flood mapping in Bangladesh.

MODIS-derived flood maps were validated using Radarsat-derived flood maps (Islam et al. 2010) for specific years. This validation task should be extended for several additional years to increase the confidence level. SAR-derived flood maps available at CEGIS would be very useful in this regard. The 2008 Midwest US floods were mapped by MODIS imagery and the results were compared with the numerical simulation results obtained from CCHE2D (Hossain et al. 2009). It is suggested that CCHE2D can be used to simulate the 2004 or 2007 flood of Bangladesh and compare the results obtained by Islam et al. (2010) using MODIS imagery. In this case, the model input and boundary conditions data for IWM models can be used.

As suggested by the proposed methods, flooding is to be divided into average, above average, and below average using some basis of statistical criteria. However, an exploration of the potential of using agricultural thresholds (defined by agricultural experience in terms of what it takes to actually affect crop yields) to define the cut-points of flood categories is recommended.

Cropping patterns in Bangladesh are much diversified. It is expected that remote-sensing data fusion techniques incorporating artificial neural networks (ANN) will produce good results. However, since there is no existing research on the application of ANN for mapping cropping patterns in Bangladesh, this task of the proposed methods involves uncertainty. A pilot study can be conducted to evaluate and understand the level of uncertainty that might occur in this task.

The socioeconomic model included in the proposed set of tasks considers generalized migration data. There is very little information about the categories of migration. To model flood-induced migration, it is very important to differentiate among temporary, permanent, and circular migrations. It is also important to separate individual migration from household migration.

Gray and Mueller (2012) recently conducted research to investigate the consequences of climate-related natural disasters for long-term population mobility in selected parts of Bangladesh. This study used survey data from more than 1700 households covering a time span of 15 years to estimate the effects of flooding and crop failures on local population mobility and long-distance migration involving multivariate event history models. The results of this study indicate that flooding has modest effects on population migration that are mainly visible at moderate intensities. This study also found that crop failure due to factors other than flooding had a stronger influence on population mobility, especially for households that are not directly affected but live in severely affected areas. These results clearly imply the need for extending the proposed methods to incorporate models capable of estimating crop failures due to other environmental factors in addition to flooding, such as drought. Like flooding, drought is also studied by remote sensing (e.g., Tucker and Choudhury 1987; Thenkabail et al. 2004). Normalized Differential Vegetation Index (NDVI) and other recently developed vegetation indices have been used to determine vegetation conditions for the assessment of crop yield (Hossain et al. 2006). Several studies investigated the potential of remote sensing techniques to study the impact of agricultural drought on crop yield in Bangladesh (e.g., Shahid and Behrawan 2008; Murad and Islam 2011). Therefore, it is expected that the proposed methods can be easily adjusted to incorporate the impact of drought as a driving factor for crop failure in addition to flooding, and characterize the population migration accordingly.

The author thanks the National Center for Computational Hydroscience and Engineering (NCCHE) at the University of Mississippi (UM) for providing necessary logistic support to write this chapter, and the University of Mississippi Geoinformatics Center (UMGC) for providing software support for processing and analyzing satellite imagery. Thanks are also due to the USGS Earth Resources Observation and Science Center for providing Landsat imagery and to CEGIS for providing Radarsat-1 SAR imagery acquired over Bangladesh. Thanks are also due to Mr G. Vance Justice Jr., hydrologist, United States Department of Agriculture, Agricultural Research Service, in Oxford, Mississippi, for help in processing and analyzing SAR imagery; Dr Faisal Hossain, associate professor, Department of Civil and Environmental Engineering, Tennessee Technological University, for helping with migration and slum cluster data of Bangladesh; Dr Greg Easson, professor and director of the Mississippi Mineral Resources Institute, and Dr Khaled Hasan, professor, Department of Geology, University of Dhaka, for helping with SAR-derived flood and crop mapping. Special thanks are due to Dr Mustafa Altinakar, research professor and director of NCCHE, UM, and Dr Yafei Jia, research professor and associate director, NCCHE, UM, for their continuous help, support, and encouragement for writing this article.

5.24.1 Introduction

Bangladesh is located in the alluvial, deltaic floodplain in the confluence of three major rivers: the Ganges, the Brahmaputra, and the Meghna. Water is the basis of living for the country's population. However, Bangladesh is located in a region that is considered as one of the most disaster prone areas in the world. Frequently, the country faces the challenge of severe flooding, drought, and cyclone-induced storm surges. Significant river bank erosion is a regular phenomenon along the large rivers. The southern part of Bangladesh is subjected to saline water intrusion in the surface as well as the groundwater systems. With increased development and population, water management has become more complicated (Haque 2008). The impacts of climate further complicate the situation. Hereafter in this chapter, as outlined in the foreword of the encyclopedia, the term 'climate' will be considered as inclusive of both change (first order moment) and variability (second order moment) within the known statistical distribution. The term 'change' will be used after climate only when a change in statistical distribution is being explicitly referred to.

Bangladesh is globally known as one of the most vulnerable countries to climate risks. The risks from climate can potentially exacerbate many of the current problems and natural hazards the country faces. Inferring from model projections alone that are outlined in the Intergovernmental Panel on Climate Change (IPCC) AR4 report, which, however, cannot be validated since they refer to the future, the following two key points summarize the current perception of climate risks in Bangladesh among policymakers: (1) floods, droughts, tropical cyclones, and storm surges are likely to become more frequent and severe in coming years (IPCC 2007); (2) sea level rise (SLR) could cause delay in flood recession, increase storm surge heights, and lead to salinity intrusion further inland. If these climate projections are overwhelmingly relied on, one may surmise that the water sector in Bangladesh is expected to be significantly affected and that it is necessary to develop and adopt an effective adaptation strategy. However, this chapter will show that a contextual overview of the key issues affecting

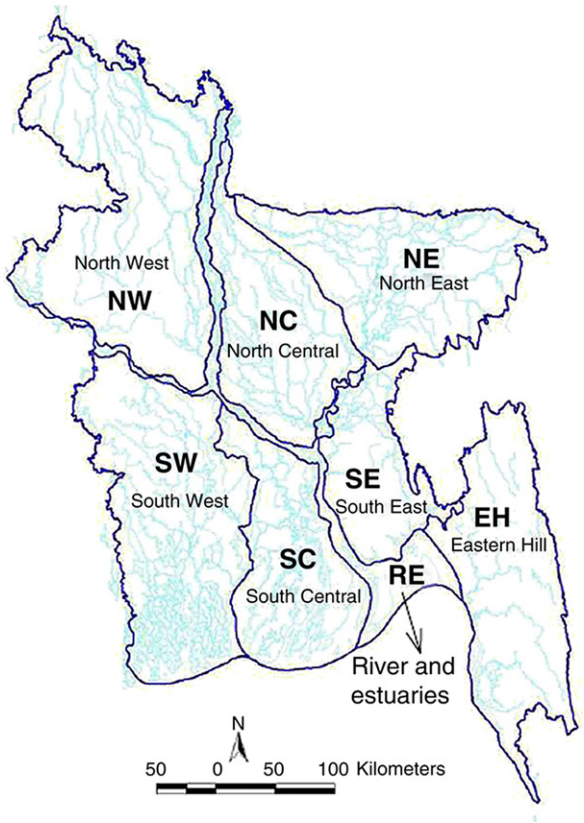

Figure 1 Hydrologic regions of Bangladesh.

water resources of Bangladesh will indeed be significantly affected from a myriad of other factors beyond those from climate risks and that it is critical to have a broader and more 'bottom up' view for formulating an effective adaptation strategy.

In this chapter, we first provide a contextual background to the important role water resources play in Bangladesh. The key environmental and socioeconomic variables that affect the country's water resources are discussed along with the sensitivity of water resources to key variables. Then, for the most sensitive variables, critical changes (thresholds) are described with associated probabilities. After that, measures that have been implemented or planned to eliminate negative impacts on the country's water resources are discussed. The chapter concludes with specific recommendations for policymakers and key stakeholders for adaptation from a bottom-up resource perspective.

5.24.1.1 Importance of Water Resources in Bangladesh

Bangladesh can be divided into several hydrologic regions (see Figure 1). The key water resources features, uses, and threats for each of the hydrologic regions are summarized in Table 1.

5.24.1.1.1 Role in Nutritional Needs (Food Security)

Bangladesh's economy is still dominated by the agriculture sector, in which irrigation production plays an important role. The food produced, mainly rice, is not only important for nutritional needs of the growing population (see Figure 2) but also valuable export income. The water

resources also play an important role in fisheries production (Figure 3). The total annual fisheries production is above 2 million tonnes year^{-1} (FAO 2012). Although production from culture fisheries (fish farms) is now dominating open-water ('capture') fisheries, the total production supports the protein needs of the population and also generates significant export income (Haque 2008).

5.24.1.1.2 Role in Water Supply

With population growth, urban and rural town water demands continue to increase. Water supply tends to be from groundwater aquifers, which are being mined in and around the major cities. However, presence of arsenic in groundwater requires a shift toward surface water resources. The seasonal nature of surface water resources and the fact that most of these resources are from transboundary rivers presents other water management challenges (WARPO 2001). About 79% of the total water used in the country is from groundwater and the remaining from surface water sources (FAO 2010).

5.24.1.1.3 Role in Economic Development

Bangladesh has managed to maintain solid economic development of the last 10–20 years (MoF 2010). Water resources have played an important role via the agriculture sector and also some water intensive manufacturing and industrial sectors. On the other hand, unchecked and rapid development in certain locations has led to acute water pollution problems. Inland water transportation is also an important communication mode in some regions. Further details in this regard can be found in Haque (2008).

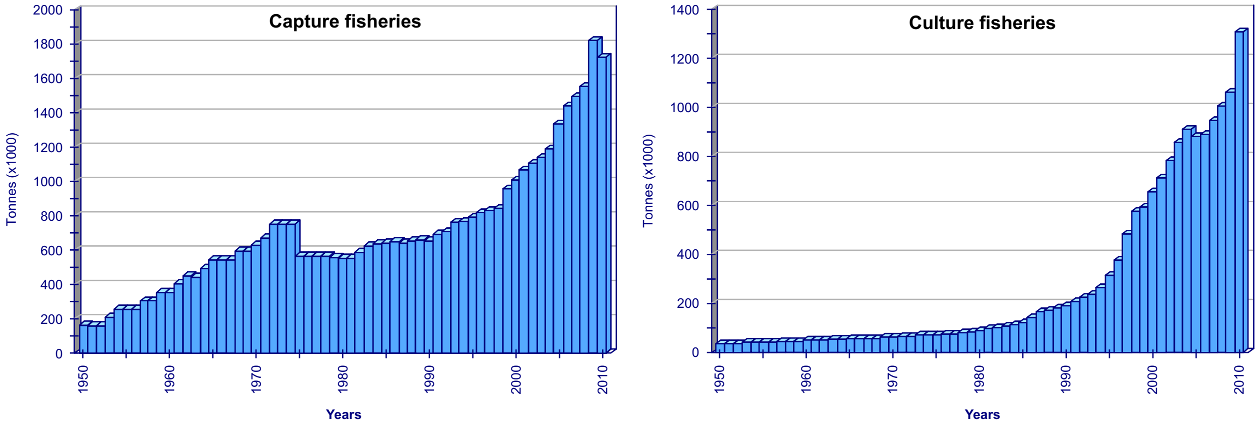

Figure 3 Fisheries production of Bangladesh. FAO, 2012: *Fishery and Aquaculture Country Profiles – Bangladesh*. Food and Agriculture Organization. [Available online at http://www.fao.org/fishery/countrysector/FI-CP_BD/3/en.]

5.24.1.1.4 Role in Ecosystem Services

The vast rivers, fertile floodplains, coastal estuaries, and eastern hills provide a richly biodiverse ecosystem. These include tropical evergreen rainforests, moist deciduous forests, mangrove forests, riparian and coastal wetlands, and the littoral, sublittoral, and benthic communities of the Indian Ocean (IUCN 2000). These ecosystems heavily depend on the monsoon rainfall, fresh river water, and the brackish coastal water resources. However, the growing population is stretching the natural resources of Bangladesh. For example, the Sundarbans forest, along the Indian border, is the largest remaining mangrove forest in the world. Several rare species of flora and fauna live in these wetlands. The Sundarbans also provides protection from storms and cyclones. However, this forest ecosystem is threatened by lack of upstream freshwater and salinity intrusion from the south.

5.24.1.1.5 Role in Natural Disasters

Bangladesh is located at the tail-end of the Ganges–Brahmaputra–Meghna (GBM) basins covering an area of around 1.72 million km^2 (Ahmad et al. 2001). Around 97% of the basin area is located outside of Bangladesh. The rivers of Bangladesh carries on an average of 180 000 m^3 s^{-1} of peak monsoon flow and 80% of the flow is generated from rainfall and snowmelt in the upstream river basins. The topography is generally flat except for the hilly terrains in the north- and southeastern parts of the country. Two-thirds of the land area of Bangladesh is less than 5 m above mean sea level. As a result, the country is susceptible to frequent inundation from rainwater and river floods (see Figure 4). Every 3–5 years, floods of devastating magnitudes inundate nearly about two-thirds of Bangladesh. Furthermore, storm surges due to cyclones also lead to flooding and salinity intrusion in coastal areas. For more information, the reader is referred to Brammer (1999) and Haque (2008).

River bank erosion is another source of disasters for the town and settlements located in and around the large rivers. Some people are forced to migrate to the cities because of river erosion. Others, especially those living on chars (sand bars), have become masters of adaptation and have a rich indigenous knowledge of the local area to cope during such disasters.

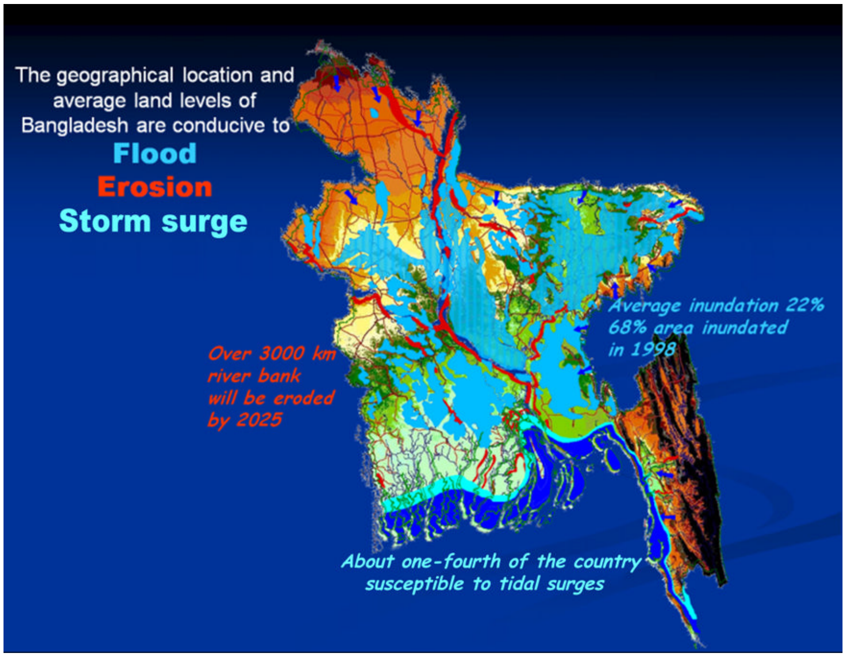
5.24.2 Sensitivity of Water Resources to Environmental and Socioeconomic Variables

Based on the previous section, the key environmental and socioeconomic variables affecting water resources in Bangladesh are summarized in Figure 5.

The relative sensitivity of water resources to the above variables are summarized in Table 2. The sensitivity is considered in two dimensions: spatial extent (i.e., How prevalent is its influence throughout the country?), and temporal extent (i.e., Is the sensitivity seasonal or more persistent?). The sensitivity has been qualitatively assessed by the authors by searching published literature and is reported at three levels: high, medium, and low.

5.24.2.1 Climate and Weather

The water resources of Bangladesh are very sensitive to the climate, which is dominated by the Indian Ocean Monsoon system. There are four meteorological seasons: premonsoon/summer (March–May), monsoon (June–September), postmonsoon (October–November), and dry/winter (December–February). Average annual rainfall is around 2300 mm,



The geographical location and average land levels of Bangladesh are conducive to
Flood
Erosion
Storm surge
Average inundation 22%
68% area inundated in 1998
Over 3000 km river bank will be eroded by 2025
About one-fourth of the country susceptible to tidal surges

Table 2 Sensitivity of water resources to environmental and socioeconomic variables

	Sensitivity of Water Resources		
Variable	*Spatial Extent*	*Temporal Extent*	*Remarks*
Climate and weather	H	H	Monsoon leads to 5 months wet season and 7 months dry season
Transboundary flows	H	H	~97% of GBM basins area located outside Bangladesh
Water demand	H	M	Large growing population and economic development increasing demands
Water policies, plans, etc.	M	H	Implementation hindered by lack of capacity at local to national level institutions
Contamination	M	M	Localized problem around industrial areas and cities/townships, particularly in dry season; arsenic problem in some regions
River alignment	M	L	Erosion and accretion affects the course of regional rivers, occurring in postmonsoon and dry seasons
Land use changes	L	L	Urbanization and other land use changes affecting runoff patterns

H = high, M = medium, L = low.

varying from 1110 mm in the northwest to 5690 in the northeast (FAO 2010). About 70% rainfall occurs during the period from June to September. Mean monthly rainfall during the same period is between 300 and 450 mm. Average humidity is close to 90% in the monsoon season (FAO 2010).

Changes in timing of the monsoon and its intensity have a major bearing on the state of water resources and consequential effects on agricultural production and other economic sectors. For example, if the monsoon arrives too early, then flash floods can occur and crops (Boro rice) can be damaged in low-lying areas (Brammer 1999; Chowdhury and Ward 2007).

Other weather events such as cyclones have major impacts on water resources in the coastal region. Storm surges during cyclones cause flooding and increased salinization in coastal areas. The coastal region of Bangladesh, covering an area of 4 million ha, is extremely vulnerable to cyclone-induced storm surges. Between the years 1877 and 2010, Bangladesh was hit by 160 cyclone events – of them 45 were severe. The severe cyclone events generated storm surges, which were sometimes more than 10 m in height. This has major impacts on infrastructure, agricultural production, and water supply.

Drought is particularly common in the Northwest region during November to April. During this period, only 20% of annual rainfall occurs and most of the regional river loses its connectivity with the major rivers. Moreover, withdrawal of water by upstream nations from the international rivers is a major problem to the sustainability of dry season flow in these rivers. Monsoon drought is also common due to active monsoon breaks. Also, extensive periods of hot weather in the summer lead to peaks in water demand, especially in the irrigation sector (WARPO 2001).

5.24.2.2 Transboundary Flows

In addition to the seasonal nature of the river flows, upstream interventions on transboundary rivers have major implications on the water resources of Bangladesh. About 97% of the GBM basins area located outside of the country. There are 57 transboundary rivers, of which 54 are shared with India and the remaining 3 with Myanmar. Similarly, many aquifers are located on both sides of the international borders. With heavy reliance on groundwater in the region due to growing water demands, particularly in the dry season, the water resources in Bangladesh are very sensitive to changes in abstraction from these aquifers (Haque 2008).

5.24.2.3 Water Demands

An increasing demand for both surface and groundwater comes from irrigation, which accounts for approximately 58% of the total demand for water (Chowdhury 2010). Fisheries, navigation, and environment sectors account for approximately 41%, while demand for household and industrial use is about 1% (Chowdhury 2010). Meeting the growing water demand in the country, driven by population growth and overall economic development, is a major challenge for water managers. In cities like Dhaka, Chittagong, and Khulna, the water supply authority is looking at tapping sources from further and further rivers. In particular areas, like Dhaka, excessive groundwater pumping has lead to significant falls in the water table. Even though Bangladesh is blessed with many rivers, the seasonal flow pattern makes it difficult to match water demands in the dry season. In order to meet the growing food demands of the population, irrigated agriculture is being intensified in various parts of the country. As a result, the water resources of the country are particularly sensitive to the changing nature and seasonality of water demands. This is one of the reasons why particular policies, plans, etc. are put forward.

5.24.2.4 Water Policies, Plans, etc.

The national water plans (NWP) of 1987 and 1988 were initiated by the government to prepare a comprehensive water master plan with a planning horizon up to 1990–2010. Despite the many limitations of the plans, both phases of the NWP made vital contributions to the knowledge and understanding of the water resources of Bangladesh.

After the disastrous floods of 1987 and 1988, a number of studies on the flood problem of Bangladesh were carried out under the flood action plan (FAP). The rehabilitation and improvement of existing schemes, rather than new development, was given attention in FAP. The FAP Summary Report, published in December 1995, presented a proposed framework and short-term (1995–2000) program for future development. This implementation program centered on the completion of FAP activities, flood proofing, river management and coastal protection, urban flood control and drainage (FCD), and water and flood management. The Bangladesh water and flood management strategy (BWFMS) was the major strategy follow-up to FAP and became the working policy document for the water sector. Many of the BWFMS concepts were carried forward into the National Water Policy, which was adopted in December 1998. The concepts advocated a more multisectoral integrated approach, which was a substantial deviation from the ideas that had dominated water sector thinking until the early days of FAP. National Water Policy insists on regional cooperation to adapt with the vulnerability of floods, drought, and cyclone through developing a system for exchange of information and data on relevant aspects of the management of flood and drought.

The National Water Resources Council (NWRC) is the highest national body for the formulation of water policy. The NWRC coordinates different water agencies and makes recommendations on all water policy issues to the cabinet. The Ministry of Water Resources plays a major planning role through the Water Resources Planning Organization (WARPO) and project implementation through the Bangladesh Water Development Board (BWDB). Other key organizations with policies, plans, projects, etc. related to water resources include the Department of Public Health Engineering (DPHE), the Local Government Engineering Department (LGED), the metropolitan Water and Sewerage Authorities, the Department of Fisheries, Bangladesh Inland Water Transport Authority (BIWTA), the Roads and Highways Department, the Department of Environment (DoE), and respective municipal authorities. The BIWTA is responsible for the maintenance of river navigation channels.

Various national level policies, plans, and projects have major influences on water resources in the country. For example, the National Water Policy and National Water Management Plan address key issues in the water sector. However, full implementation of all key policies and plans have been generally difficult for various reasons, e.g., funding limitations, lack of institutional capacity, resistance from different interest groups, etc. Also, a lack of integration of polices and plans related to water resources hinders positive outcomes.

5.24.2.5 Contamination

Water resources of Bangladesh are sensitive to contamination by human practices and also from natural sources. Rapid economic development and a general disregard for environmental stewardship have lead to contamination of surface and groundwater resources. The situation becomes particularly bad during the dry season. Although the monsoon flows help dilute pollution levels in surface water resources, groundwater contamination persists throughout the year. The presence of arsenic in groundwater from geological formations in various regions around the country is an example of natural contamination. There is also contamination caused by a combination of human actions and natural processes. For example, salinity intrusion in coastal rivers, mainly a dry season phenomenon, is affected not only by upstream flow changes but also by natural advection and dispersion processes (RRI and SWMC 1993).

5.24.2.6 River Alignment

The delta that forms Bangladesh is still active and there are high rates of erosion and sedimentation, which regularly alters river alignment in various parts of the country. Thus, changes in river alignment also affect water resources in Bangladesh. For example, anabranches and bends get cut off due to silt deposits creating lakes. Also, distributaries get cut off due to siltation at outfalls from the main channel and there are no freshwater flows into that channel. This is the case of the Gorai River, which is cut off from the Ganges River for about 5 months of the year and this results in significant salinity intrusion into in the Southwest region. Erosion can also lead to shifts in flow from one channel to other channels. Changes in river alignment tend to occur in monsoon (due to erosion) and postmonsoon (due to sedimentation) times (Mohiuddin 2011).

5.24.2.7 Land Use Changes

In various parts of the country, water resources are being affected by land use changes in catchment areas. Agricultural land is being converted to residential and industrial land due to developmental pressures. This is particularly prevalent near urban growth centers. These changes not only impact surface runoff patterns but also affect groundwater recharge processes. Also, agricultural land has been converted to roads and are built on embankments, which has impacted flow patterns in floodplains. In eastern regions, clearing of forests and cutting of hills are impacting the runoff process. These changes are not extensive compared to the total area, and the temporal extent of impacts on water resources are generally seasonal or of shorter duration (Haque 2008).

5.24.3 Critical Changes (Thresholds) in Variables Affecting Water Resources

As discussed in the previous section, the water resources of Bangladesh are particularly sensitive to changes in the following variables:

- Climate and weather
- Transboundary flows
- Water demand
- Water policies, plans, etc.
- Contamination

In this section, critical changes in each of the above variables are identified and discussed. A simple framework for identifying when and where changes are critical has been used (see Figure 6). The framework takes into account variability (seasonal and long term) in environmental variables (e.g., flood flows) and also changes (short- and medium term) in socioeconomic variables (e.g., population growth). These factors are then considered in a spatial context, e.g., large flood flows in areas with relatively low population densities are less critical than those in high population density areas. The combination of these spatial and temporal factors combine to determine whether a change in the variables affecting water resources are critical or not, i.e., whether the change results in significant risks or hazards on the water resources.

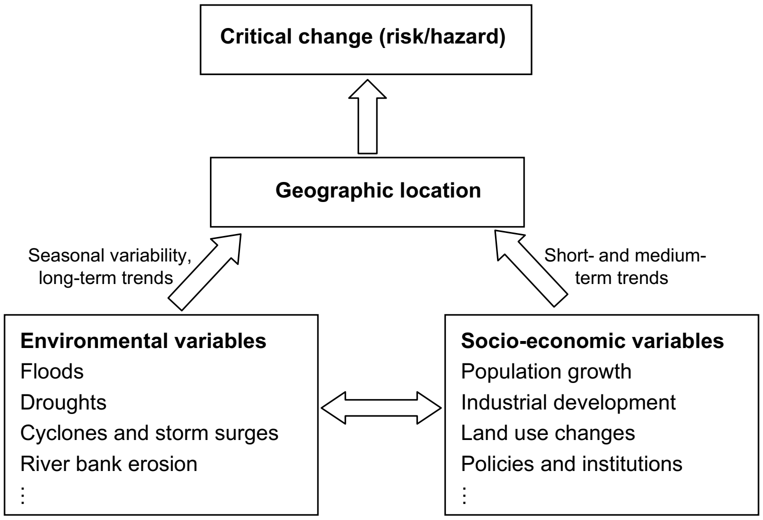

Figure 6 Framework for identifying critical changes in variables.

Where possible, particular thresholds that lead to positive (or negative) impacts on water resources are highlighted from published literature or ongoing studies. Where appropriate, critical changes to the state of the water resources have been investigated using a set of computer models. A brief description of the models used is given in Table 3.

5.24.3.1 Climate and Weather

An overall increase in the mean seasonal rainfall has been observed for all seasons, except for the monsoon season (CCC 2009). Similar findings were reported by Rahman et al. (1997), Singh and Sontakke (2002), and Mondal and Wasimi (2004). These decreasing monsoon and increasing winter rainfall trends are contrary to IPCC's (2007) AR4 projections. A more detailed study of rainfall patterns suggests a decrease in the early part of monsoon (June–July) and an increase in the later months (September–October) (CCC 2009). Thus, a shifting of seasons could be occurring. Also, there is evidence of increased intensity of monsoon rainfall along the path of the south–westerly monsoon winds (over Chittagong, Sylhet, Mymensigh, and Bogra) (CCC 2009). These changes in the monsoon timing have major impacts on the cropping cycle and also on fish breeding patterns.

The frequency of extreme rainfall events has also increased over the recent years. The highest recorded rainfall for any month in the capital for a 24-h period was 341 mm in September 2004. Again, more recently, 448 mm of rainfall was recorded during 24 h in Dhaka on 27 July 2009, which was the highest recorded event in the capital. In fact, 290 mm of rainfall was recorded during 8 h from 11 pm on 27 July to 7 am on 28 July 2009. The previous 24-h record for Dhaka in July was 326 mm in 1956. The increasing frequency of extreme rainfall events is leading to increased localized flooding especially in urban areas and flash-flood prone areas in the Northeast region (Rahman et al. 2005; CCC 2007).

Analysis of temperature from different stations in Bangladesh from 1948 onward shows a clear sign of change and variability (see Figure 7). Khan et al. (2000) analyzed sea-surface temperatures (SST) for May and November (cyclone seasons) at two coastal stations for the period 1985–98. At Hiron Point, the average temperatures increased by 1 and 0.5 °C in May and November, respectively. At Cox's Bazar, the corresponding SST increased by 0.8 and 0.4 °C. In a more recent study, Bangladesh's Climate Change Cell (2009) also reported that mean temperatures across the country have been increasing for all seasons. It is interesting to note that the temperature increase is higher in a more recent period compared to the longer period, as shown in Table 4. It should be noted for future policymaking, that more rigorous statistical analyses (such as *t*-test, Mann–Kendall test, etc.) are required to establish where this change is significant before formulating any strategy.

Temperature increases in the Himalayan region will be critical for water resources in Bangladesh. This is because the corresponding increase in snowmelt will lead to more runoff from mountain regions. When this is added to an increasing trend in monsoon rainfall, the flooding situation in the country can considerably worsen.

5.24.3.2 Transboundary Flows

Around 80% of flow through Bangladesh originates from upstream catchments in India, Nepal, Bhutan, and China. The Ganges, Brahmaputra, and Meghna (GBM) rivers carry this flow through Bangladesh to the Bay of Bengal. The combined discharge of water from the GBM rivers is second only to that of the river Amazon. These rivers discharge 1.5 $\mathrm{Mm^3\,s^{-1}}$ during the peak period (Hasan and Mulamoottil 1994). In the low season, the runoff is only about 61 000 $\mathrm{m^3\,s^{-1}}$ (Hasan and Mulamoottil 1994). The ratio of peak to low season flow is approximately 25:1. Almost 85% of the mean dry season stream flow is found in the GBM rivers (World Bank 2000). The Brahmaputra accounts for 67% of the flow measured within the country, whereas the share of the Ganges is only 13% (Hasan and Mulamoottil 1994). The Meghna contributes only 2% of the total measured discharge in Bangladesh during March.

Analysis of trends in the river flow in the GBM rivers is not straightforward because sufficient data are not available to

Table 3 Models used to analyze critical changes in water resources

Model	*Description*
Model of the GBM basins	The model covers the entire area of the GBM river basins of 1.64 million km^2 and extends into India, Nepal, Bhutan, and China. This model has been used to simulate the changes to the transboundary flow into Bangladesh. The projected rainfall and temperature from the General Circulation Models has been used as input to the basin model to project the inflow from the basins into Bangladesh assuming hypothetical scenarios that cannot be validated.
Hydrodynamic model of Bangladesh – the super model	The super model of Bangladesh is a detailed hydrodynamic model of all significant rivers and the floodplain system of Bangladesh. The inflow predicted by the GBM basins model has been used as a boundary condition for this model. This model simulates water level and discharge in the river system at 12 000 computational grids. The geographic information system interface allows for generating the flood maps. The downstream (sea boundary) boundary conditions are tidal water levels generated by adding the SLR with the actual or computed tidal water levels.
Salinity intrusion model	The salinity model covers the entire tidal area of Bangladesh. The model can simulate salinity concentration at various locations. This model takes the upstream inflow and downstream tidal boundary as boundary conditions. Impacts on salinity concentration due to any change to the upstream and downstream boundary conditions can be simulated by this model.

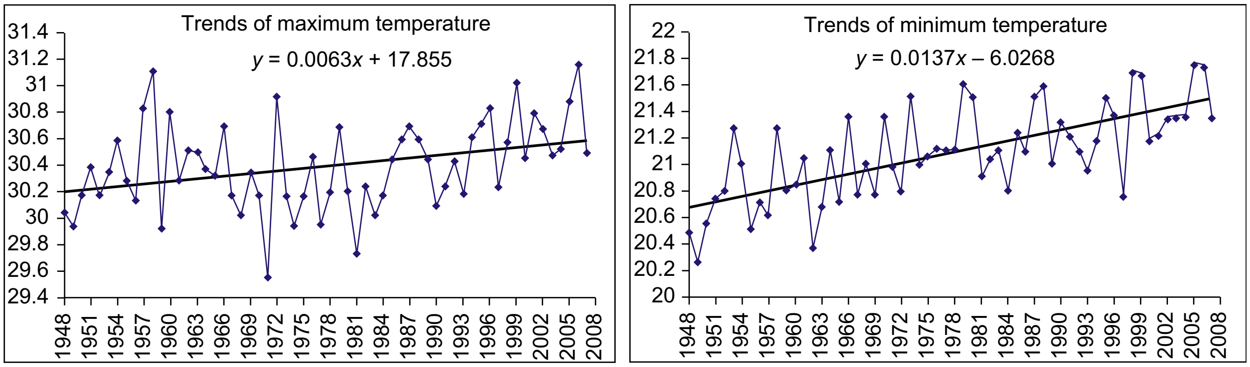

Figure 7 Trends of temperature in Bangladesh based on historical data. CCC, 2009: Characterizing Long-term Changes of Bangladesh Climate in Context of Agriculture and Irrigation. Climate Change Cell, DoE, MoEF; Component 4b, CDMP, MoFDM. Month 2009, Dhaka.

Table 4 Mean seasonal temperature trends in Bangladesh

	Trends in Bangladesh mean temperatures (°C per century)	
Season	*1948–2007*	*1980–2007*
Winter (Nov–Feb)	+1.67	+1.33

separate the anthropogenic and climatic factors that are responsible for such a trend. However, the sequence of development in the Ganges basin gives us some idea of the anthropogenic factors:

1949–59: Initiation of major development works in the Ganges basin but the Ganges basin was still very near to its natural state without significant interventions.
1960–74: Pre-Farakka period from 1960; major storage and diversion projects commissioned.
1975–96: Pre-Ganges Water Treaty (GWT) period from the commissioning of Farakka barrage.
1997–2007: Post-GWT period.

During the period 1949–2005, the mean annual flow volume at Hardinge Bridge on the Ganges River was about 365 458 MCM (million cubic meter) with a range of 201 293–528 518 MCM. The lowest volume of water available was in 1992 and the highest in 1956. The available data indicate a slightly increasing trend of Ganges flow in the 1949–59 period at Hardinge Bridge. As shown in Table 5, during 1960–74 and 1975–96, flow volumes at Hardinge Bridge shows a decreasing trend in both the dry (Nov–Apr) and wet (Jun–Oct) periods. As shown in Figure 8, there is a decreasing trend of flow in both the dry and wet periods observed for the Ganges River at Hardinge Bridge. The ratio between the discharges of the dry and monsoon seasons for the Ganges River is 1:6 (World Bank 2000).

During the period 1960–2005, the mean annual flow volume of the Jamuna River at Bahadurabad was about 640 568 MCM, which varies from 515 392 to 864 023 MCM. The lowest volume of flow was available in 1986 and the highest in 1990. The available data for the Brahmaputra (i.e., Jamuna) at Bahadurabad from 1960 to 2005 indicate that the average dry season flow represents only 16% of the total annual flow (see Table 6). An increasing trend of flow in both dry and wet periods is observed for the Brahmaputra River at Bahadurabad (see Figure 9).

Natural calamities in Bangladesh result in major economic and social impacts and loss of life. The 1998 floods, which inundated two-thirds of Bangladesh, caused a loss of 5.5% of Gross Domestic Product (GDP) (see Table 7). It is interesting to note that the next major flood (in 1998) had a larger return period and more area was affected, but compared to the 1988 flood, less people were affected (and killed), less houses and crops were damaged, and asset losses (as percentage of GDP) were also less. This suggests that warning systems and other lessons learnt were successfully implemented after the 1988 flood. However, the length of roads damaged increases in time,

even for smaller flood events. For example, comparing the impacts of 1998 flood with 2007, one can see that the length of roads damaged almost doubles in 2007 even though it is a considerably smaller flood. In fact, in 2007, the number of fatalities and crops damaged also increased compared to 1998. This was likely due to the increase in population and expansion of agricultural activities: more and more human habitation and farms are located in the floodprone areas because of tremendous pressure on land. As a result, risks to human life and the economy have increased. It is envisaged that the risk will further increase from climatic impacts in terms of increased flooding, waterlogging, storm surge, drought, and salinity intrusion. This makes Bangladesh one of the most vulnerable countries to climatic impacts. The Sidr cyclone of 2007 resulted in a loss of 2.6% of GDP. On average, loss of GDP due to natural calamities ranges between 0.5 and 1% of the country's GDP. However, as shown in Table 7, the percentage of GDP affected due to major floods is decreasing, which suggests that the national economy is becoming more robust to such disasters.

5.24.3.3 Water Demands

In terms of water availability, March is a critical month in the country as irrigation demands are highest and surface flows are very low. Irrigated agriculture is the major water-using sector with rice cultivation being the single most important economy activity. The cropping calendar is based on the temporal distribution of rainfall and temperature throughout the year. In most areas, aus rice is the premonsoon crop; aman is the monsoon rice; and boro rice is grown in the dry season with irrigation. Aman is generally the main rice crop occupying the area, followed by boro; and then aus. Aus rice has reduced in importance after the introduction of high yielding varieties of boro rice. This continues to have a major impact on water resources, as the demand for water from agriculture in the dry season has been increasing. In the future, agricultural demand for water is likely to increase due to further irrigation expansion. It has been estimated that irrigated area may increase to about 7 million ha by 2020 (World Bank 1998). This would be a critical change in water demand.

Although, at present, irrigated agriculture is the main water user, demand from urban areas is increasing due to overall national population growth (see Table 8). Economic growth is also leading to increases in industrial water demands. It is likely that the water supply for domestic and industrial usage will require a reduction in groundwater irrigation in many areas. The National Water Policy gives the agriculture sector a relatively low priority and sets the following order for water usage: domestic and municipal uses, nonconsumptive uses (e.g., navigation, fisheries, and wildlife), river regime sustenance, and other consumptive and nonconsumptive uses including irrigation, industry, environment, salinity management, and recreation (WARPO 2001). The shift of water use away from agriculture could be a critical positive change in water demands, as this could free up vital resources in certain areas.

5.24.3.4 Water Policies, Plans, etc.

Several key laws, policies, and plans directly related to water resources have been developed since the mid-1990s: Environment Conservation Act (1995), National Environment Management Action Plan (1995), National Policy for Safe Water Supply and Sanitation (1998), National Fisheries Policy (1998), National Water Policy (1999), National Water Management Plan (2004), and National Arsenic Mitigation Policy (2004).

There have also been many laws, policies, and plans that are indirectly related to water resources: National Environment Policy (1992), National Environment Action Plan (1992), National Agriculture Policy (1994), National Forest Policy (1994), National Energy Policy (1996), Forestry Master Plan (1993–2012), Sustainable Environment Management Program (1997), and National Conservation Strategy (2005).

The National Water Management Plan (NWMP) (2004) provides a framework for 24 line agencies and other organizations to plan and implement their activities in a coordinated manner. The NWMP is a rolling plan to be reviewed and updated every 5 years. However, a formal review has not yet been conducted. This highlights the difficult problem of updating and implementing well-meaning policies, plans, and laws. This results in continuing deterioration of the water resources around the country.

There have been many major water engineering projects implemented throughout the country, e.g., flood control and drainage projects. The cumulative effects of these human interventions have had major impacts on the country's water resources. The BWDB is responsible for the planning and execution of over 400 projects related to flood control, drainage, irrigation, coastal protection, and erosion control. Major investments in the water sector are made by the Ministry of Water Resources through the BWDB. For example, the BWDB is undertaking a feasibility study and detailed engineering design for constructing a barrage on the Ganges River (Government of Bangladesh 2005). The BWDB also plays a vital role in collecting hydro-meteorological data from its numerous measuring stations around the country.

Relatively smaller scale projects are executed by the LGED. Another major executing agency is the DPHE, which is responsible for managing projects related to water supply and sanitation in rural areas and towns. Currently, DPHE is developing water supply and sanitation master plans for 148 towns around the country. In city areas, there are water supply and sanitation companies mandated to service metropolitan areas.

This includes abstraction and treatment of water from surface and groundwater sources and also treatment and discharge of wastewater.

Quite often it is found that structures built to control floods in one area have aggravated the problems in others and hampered agriculture, fishing, and navigation activities. Given the differential needs of the various water management issues, improved coordination of the activities of relevant agencies will lead to better plans and projects.

5.24.3.5 Contamination

Critical changes in contamination include variations in urban pollution levels and salinity intrusion in coastal areas. Urban pollution impacts water resources mainly during the dry season and in localized areas. Laws, policies, and plans are already in place to limit this threat to water resources (as discussed in the previous section).

Recent measured data (2005–09) have shown a clear increasing trend in river salinity in the southwest region (see Figure 10). Around 15 500 km^2 of coastal area experiences salinity in excess of 1 ppt in the surface water during April and May every year. The extent of salinity in the groundwater system could not yet be quantified, but it is understood from data from different sources that out of 19 coastal districts, 50% have salinity above 1 ppt at various aquifer units. No sufficient data exist to exactly identify the cause of such increasing trends, but it is widely assumed that freshwater withdrawal in the upstream has probably caused the increase in salinity over the years.

In the future, another reason for increased river salinity could be due to SLR. The salinity model of Bangladesh built by Institute of Water Modeling (IWM) has projected significant impact on salinity intrusion in the coastal region of Bangladesh. Due to an SLR of 60 cm, the saline front could intrude a maximum of around 55 km inland. For an additional 60 cm rise in sea level, the saline front would further propagate 40 km (Figures 11 and 12). This may cause major havoc in the coastal economic and ecological systems.

An increase in river salinity has major implications to the water supply, soil salinization, aquifer salinization, and ecosystem. It is likely that sea level rise and increase in storm surges will exacerbate the situation in the future.

5.24.4 Impacts of Critical Changes and Actions to Eliminate Negative Impacts

The main critical changes to water resources in the country are listed in Table 9. In order to further prioritize these critical changes, a simple risk assessment method has been used by the authors. The risk has been assessed for each critical change based on its potential impact on water resources and also its likelihood. A risk score is calculated by multiplying the impact score with the likelihood score. The impact and likelihood scores have been provided by the authors based on experience in the water resources field.

After highlighting some key sectoral impacts of the above critical changes in water resources, a discussion of some of the main adaptations that have been adopted is provided. In general, in Bangladesh adaptation is undertaken at a local scale and, in fact, has adopted a very bottom-up contextual approach since the 1960s.

5.24.4.1 Sectoral Impacts

The consequences of changes in the water regimes on other economic and biophysical sectors are often nonlinear, complex, and difficult to distil from anthropogenic influences. During the last decade, comprehensive research, studies, information, and tools on climate and its impacts have become available and understanding of the processes, pathways, and consequences has improved. Different studies show that in Bangladesh the sectors that are predicted to be the most affected by changes in water and water resources are agriculture, health, fisheries, biodiversity, and infrastructure. The impacts of climate on different sectors and systems through water are listed in Table 10.

Table 9 Summary of key risks to water resources

Variable	*Critical change*	*Impact on water resources*	*Likelihood*	*Risk score (impact × likelihood)*
Climate and weather	Timing of monsoon	3	2	6
Climate and weather	Increased rainfall intensity	3	3	9
Climate and weather	Increased temperatures	2	3	6
Transboundary flows	Ganges flow decrease	3	2	6
Transboundary flows	Ganges flow increase	3	2	6
Transboundary flows	Brahmaputra flow decrease	3	1	3
Transboundary flows	Brahmaputra flow increase	3	3	9
Transboundary flows	Meghna flow decrease	3	2	6
Transboundary flows	Meghna flow increase	2	2	4
Water demands increase	Agricultural demands	3	2	6
Water demands increase	Urban demands	2	3	6
Water policies, plans, etc.	Poor implementation	3	2	6
Contamination	Increase in river salinity	3	3	9
Contamination	Increased urban pollution	2	2	4

Score definitions–impact: 3 = major, 2 = moderate, 1 = minor; likelihood: 3 = very likely, 2 = possible, 1 = small chance; risk: <3 = low, 3–4 = medium, ≥ 6 = high.

The people of Bangladesh have adapted to the risk of floods, droughts, and cyclones over the generations. In Bangladesh water resources management systems have focused on the need to regulate and distribute water for irrigation, food production, and water supply, and flood defense and drainage measures were taken to reduce flooding damage. But increased pressures on water resources from high population density, poor infrastructure, and low resilience to economic losses are now compounded by uncertainties of climate variability. This means the present approaches and traditional methods of water resources management systems need to be reassessed. New approaches, knowledge, and technology need to be considered for improved adaptation to climate variability.

Over the last 50 years, major investment has been made to reduce the climate-related vulnerability of people and economic resources in Bangladesh. These include both structural and nonstructural measures. Around 1.75 million ha land in the coastal areas has been empoldered (155 polders) to protect the area from salinity intrusion and tidal inundation. More than 5000 cyclone and flood shelters have been constructed. Around 4 million ha have been brought under flood management schemes (266 schemes). Most of the major roads and highways have been raised above flood levels. A very comprehensive disaster management and flood warning system covers all of Bangladesh (DMB 2010). Climate resilient varieties of rice and other crops have also been developed. These measures have surely made Bangladesh more resilient of climate-related hazards, but more still needs to be done in view of the expected climate variability impacts and sea level rise.

5.24.4.2 Flood Management

Since ancient times, life in Bangladesh has been centered on the numerous rivers, the annual cycles of flooding, and the hydrological characteristics of the country. The modern period efforts for flood management public initiatives began in 1957, with the appointment of the Krug Mission in the wake of the devastating floods in 1954, 1955, and 1956. At the request of the then Government of Pakistan, the United Nations sent this technical assistance mission, which emphasized the need for flood control to increase agricultural production. The East Pakistan Water and Power Development Authority, now known as Bangladesh Water Development Board, was created in 1959 and was responsible for the planning, design, operation, and management of all water development schemes. Consequently, a Master Plan for water development formulated in 1964 included a portfolio of 58 land and water development projects for implementation spread over 20 years. On the basis of this plan, large-scale land and water development schemes were initiated by the government (Datta 1999).

In 1972, the Land and Water Sector Study, on the other hand, emphasized agricultural production rather than flood control and underlined the need for considering land and water as integrated resources. Recommendations included the development of minor irrigation through low lift pumps and tube wells supported by complementary less capital and labor intensive FCD projects.

Embankment construction has been the major activity in these FCD projects as part of the comprehensive flood and land management strategy. Embankments of a total length of more than 8300 km have been constructed since 1959 in the country. Flood protection for major cities, important commercial and industrial areas, and key transport and communication infrastructure are given the highest priority. This is reflected in the design of the embankments surrounding the four major cities, Dhaka, Chittagong, Khulna, and Rajshahi urban areas. A 100-year flood frequency was adopted as the design water level for urban settlements, whereas the embankments protecting agricultural areas are normally designed for a flood of 25-year frequency.

Over the past three decades, flood, considerable change, and progress based on practical experience and lessons learned can be seen in the planning and implementation of these projects. Emphasis is on a more comprehensive approach with multiobjective and multisectoral planning, rather than single-objective (e.g., food grain self-sufficiency) planning. The generally better performance of small-scale interventions and private sector development has seen reduced importance of large scale government projects. Stakeholder participation and consultation at all levels and from the private and Non-governmental Organization (NGO)

Table 10 Examples of major impacts by sector mainly through water resources

Variable	*Water resources*	*Agriculture*	*Health*	*Biodiversity*	*Industry and infrastructure*
Increased temperature (warmer and humid weather)	Increased water temperatures Increase in evaporation Earlier snow melting Increased algae growth reducing dissolved oxygen levels in water body Changes in mixing patterns and self-purification capacity of water bodies	Less water available for agriculture, more irrigation needed Changes in crop productivity Changes in growing season	Changes in vector-borne diseases Increase of fatalities due to heat waves, and decreased personal productivity Increased risk of respiratory and skin diseases	Changes in species composition, organism abundance, productivity and phenological shifts, for example, earlier fish migration Eutrophication and loss of fish	Degradation of freshwater quality
Increase in heavy precipitation events and more erratic behavior	Flooding Drainage congestion Higher river flows	Damage to crops Soil erosion Inability to cultivate land due to waterlogging of soils	Increased risk of deaths, physical injuries and infections, respiratory and skin diseases Risk of psychological disorders	Damage to habitat Additional flooding adversely affecting vegetation	Disruption of settlements, commerce, transport, and societies due to flooding and migration Pressures on urban and rural infrastructures Loss of property
Higher variability of precipitation including increased droughts	Changes in runoff More widespread water stress Increased water pollution due to lower dissolution of sediments, nutrients, dissolved organic carbon, pathogens, pesticides and salt, as well as thermal pollution	Land degradation Lower yields/crop damage and failure Increased livestock deaths	Increased risk of food and water shortage Increased risk of malnutrition Increased risk of waterborne and food-borne diseases	Water stress will damage habitat and ecosystems (e.g., forest ecosystems in Madhopur and Barind Tract) Causing decline in fisheries stock	Water shortages for settlements, industry, and societies Reduced hydropower generation potentials Potential for population migration
SLR	Salinity intrusion (more areas affected, longer duration of saline intrusion, and higher concentration) Drainage congestion Coastal erosion	Less freshwater available for agriculture and livestock Inability to cultivate land due to waterlogging of soils Loss of agricultural land	Changes in vector-borne diseases Increased heart diseases especially in pregnant women	Loss of habitat for freshwater species	Degradation of freshwater quality for settlements, industry, and societies
Increased frequency and severity of cyclones and storms	Higher storm surges Salinization of water bodies and aquifers	Damage to crops and livestock	Increased risk of malnutrition Increased risk of waterborne diseases	Damage to habitat, vegetation, and animals	Disruption of settlements, commerce, transport, and societies due to flooding and migration Loss of property

Adapted from UNECE, 2009: Convention on the Protection and Use of Transboundary Watercourses and International Lakes. Guidance on Water and Adaptation to Climate change, United Nations Economic Commission for Europe; MoEF, 2009: Bangladesh Climate Change Strategy and Action Plan 2009. Ministry of Environment and Forests, Government of the People's Republic of Bangladesh, Dhaka, Bangladesh.

sectors as well as the public sector are now recognized to be essential (WARPO 2001). Low-cost activities, such as structural flood proofing and nonstructural measures, are now advocated for rural areas, which are not of high economic importance with urban FCD, are now being given more emphasis than in the past. Present integrated water and land use planning is set to focus on the development of floodplain zoning to accommodate necessary engineering measures and allocate space for habitation patterns, economic activities, and environmental resources.

5.24.4.3 Recent Water Policies, Plans, etc.

The Bangladesh government is very much concerned about climate risks, and this is reflected in several policies that relate to climate variability and water resources management. Bangladesh has a National Adaptation Program of Action (NAPA) (MoEF 2005) and the Bangladesh Climate Change Strategy and Action Plan (BCCSAP) (MoEF 2008, 2009). The NAPA was prepared through a series of national and subnational workshops. It lists 15 adaptation strategies, with water sector related measures such as (MoEF 2005):

- Providing drinking water to coastal communities affected by saline intrusion
- Capacity building for integrating climate variability in planning, designing of infrastructure, conflict management, and land–water zoning for water management institutions
- Information dissemination on climate variability and adaptation to vulnerable communities for emergency preparedness measures and raising awareness on climatic disasters
- Construction of flood shelters and an information and assistance center to cope with recurrent floods in major floodplains
- Mainstreaming adaptation of climate variability into policies and programs in different sectors (focusing on disaster management)

The NAPA is an integral part of national development policies, plans, and programs. The BCCSAP (MoEF 2009) builds on the NAPA and it guides actions in all areas related to climate variability. The strategy contains 44 programs formulated around six pillars: (a) food security, social protection, and health, (b) comprehensive disaster management, (c) infrastructure, (d) research and knowledge management, (e) mitigation and low carbon development, and (f) capacity building and institutional strengthening. The BCCSAP has been developed by the Government of Bangladesh in consultation with civil society, including NGOs, research organizations, and the private sector.

The Coastal Zone Policy (2005) provides general guidance for the management and development of the coastal zone in a manner so that coastal residents are able to pursue their life and livelihoods within a secure and conducive environment. The Integrated Coastal Zone Management Program (2004) identified critical impacts of climate variability and SLR, such as increased drainage congestion, reduced freshwater availability, disturbance of morphological processes, and increased intensity of extreme events and disasters.

Bangladesh has also motivated neighboring countries to actively seek adaptation options to climate variability at the regional level. This is reflected in the Sixteenth South Asian Association for Regional Cooperation summit held in Thimphu, Bhutan, in April 2010. The Thimphu statement on climate gives high priority toward preserving and sustainably managing the rich, fragile, and diverse ecosystems of South Asia and expresses deep concern about the adverse effects of climate and its impact on the region (SAARC 2010).

Other policies addressing climate variability also include the National Conservation Strategy and the Poverty Reduction Strategy Paper. Also, the Water Supply and Sanitation Sector Development Plan was finalized in 2011. This represents a new approach by the Government to integrate strategies for a sector across various administration levels. Furthermore, the Dhaka Wastewater Master Plan will be finalized in 2012, which, if successfully implemented, can lead to a major improvement in the quality of the capital's peripheral rivers.

5.24.4.4 Other Adaptation Measures

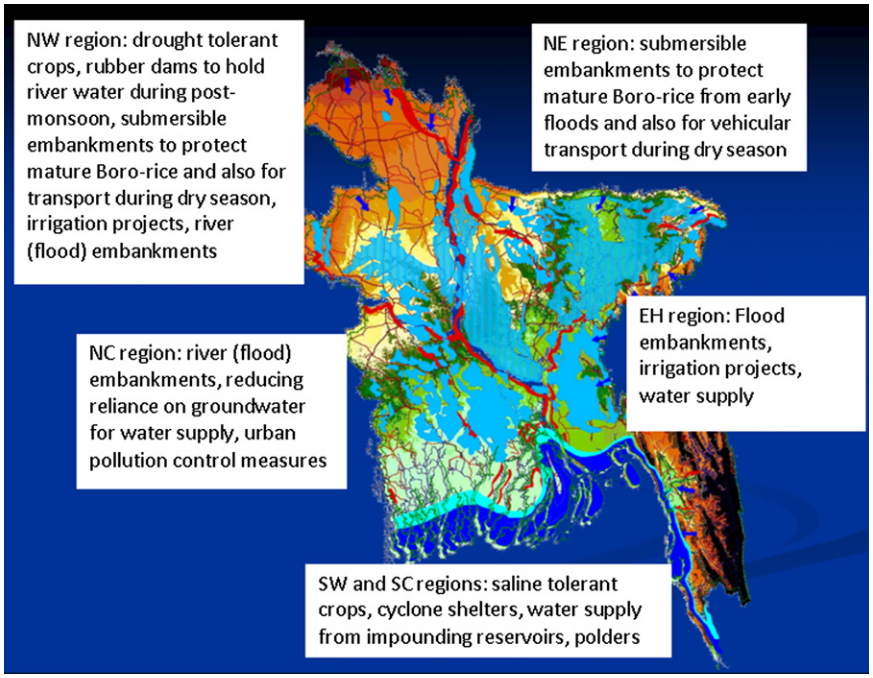
Under various initiatives, adaptation measures against various climate variability impacts have been implemented (see Figure 13).

Over 2000 cyclone shelters have been built to provide refuges for communities from storm surges caused by tropical cyclones and 200 shelters from river floods (MoEF 2009). Additional cyclone and flood shelters need to be constructed due to population increases.

There are ongoing agricultural research programs looking to develop saline, drought, and flood-adapted high yielding varieties of rice and other crops (MoEF 2009), as well as irrigation schemes to enable farmers to grow a dry season rice crop in areas in drought-prone areas (MoEF 2009). There are also flood management schemes to raise the agricultural productivity of many thousands of hectares of low-lying rural areas and to protect them from extremely damaging severe floods (MoEF 2009). Coastal embankment projects, involving over 6000 km of embankments and polder schemes, were designed to raise agricultural productivity in coastal areas by preventing tidal flooding and incursion of saline water (MoEF 2009). Where these polders are not properly designed, increased monsoon intensity can worsen internal waterlogging/drainage problems. This could be a potential example of 'mal-adaptation' (i.e., bad adaptation or adaptation gone wrong). Polder embankments also need to be redesigned to deal with storm surges with SLR. Storm surge modeling will help target adaptation efforts, surge forecasting, and disaster preparedness.

Some coastal regions, including polder areas, suffer from drainage congestion problems. This problem is likely to worsen with increased SLR. Tidal dredging is an innovative method that can help adaptation to increase capacity of coastal drainage channels and thus reduce the impact of SLR on drainage congestion in coastal areas. Redesign of drainage infrastructure will also be required. In critical locations pumping needs to be considered.

Recently, comprehensive disaster management projects, involving community-based programs and early warning systems for floods and cyclones, have been implemented (MoEF 2009). There are also specific programs for implementing drinking water and sanitation projects in areas at risk from climate variability (e.g., coastal areas, flood- and drought-prone areas) (MoEF 2009).



NW region: drought tolerant crops, rubber dams to hold river water during post-monsoon, submersible embankments to protect mature Boro-rice and also for transport during dry season, irrigation projects, river (flood) embankments

NE region: submersible embankments to protect mature Boro-rice from early floods and also for vehicular transport during dry season

EH region: Flood embankments, irrigation projects, water supply

NC region: river (flood) embankments, reducing reliance on groundwater for water supply, urban pollution control measures

SW and SC regions: saline tolerant crops, cyclone shelters, water supply from impounding reservoirs, polders

Figure 13 Location and main adaptation measures in Bangladesh.

Through technical support from organizations such as IWM, Center for Environmental and Geographic Information systems, and Institute of Water and Flood Management, there is better integrated water resources management, where conjunctive use (water from surface and ground sources) is properly implemented and also proper planning is undertaken with the use of sound information and reliable decision-making tools.

5.24.5 Specific Recommendations for Policymakers and Stakeholders

In this chapter, we have presented a contextual, bottom-up approach, for identifying and prioritizing adaptation measures. In this regard, it is important that adaptation strategies are cognizant of local issues and threats in addition to climate risks (whether from projected model-based risks or otherwise). Water resources play critical roles in Bangladesh's environmental, social, and economical systems. At the same time, the country's water resources are sensitive to natural and socioeconomic variables. In this regard, the key variables are seasonal and long-term climate variability; transboundary flows (surface and groundwater); water demands (increasing trend and changing nature); local to national level policies, programs, and projects; and contamination (from industry and natural sources).

Using a framework based on bottom-up analyses, critical changes in the key variables were identified. The framework took into account temporal and spatial changes in the key natural and socioeconomic variables. Using this approach, it was possible to highlight critical changes in climate and weather patterns, such as monsoon rainfall timing, and increases in temperatures and drought conditions, which have major impacts on agriculture and fisheries sectors – key components of Bangladesh's economy. Apart from climate, the other key threats to water resources in Bangladesh are:

- Population growth (leading to higher water demands)
- Fast economic development (increasing water demands and causing localized pollution problems)
- Changes in upstream flow conditions in transboundary rivers
- Salinity intrusion in coastal rivers

The observed and anticipated change in the climatic drivers will not only disrupt the supply side in terms of freshwater availability considering floods, droughts, sediments, and drainage issues, but also will disturb the demand side in terms of irrigation, fisheries, navigation, and domestic and industrial usage.

From the analysis of existing water sector policies and plans, in relation to possible adverse impacts of climate variability, there needs to be more effective mechanisms to deal with climatic change. Policy reform to tackle climatic concerns can evolve from an increased understanding of climate variability processes, mitigation, and adaptation options. Again, experience from case studies in other countries might be useful for policy directions.

5.25.1 Introduction

On 28 July 2009, a storm system spanning an area of about 3000 km^2 over the central region of Bangladesh resulted in a very heavy downpour. In just 6 h, Dhaka city, the capital of Bangladesh (**Figure 1(a)**), received about 448 mm of rain. In a city where urban planning, drainage, and natural wetland storage have been compromized by rapid urbanization, such a massive downpour resulted in catastrophic inundation of the city in a matter of hours (The Daily Mail 2009; **Figure 2**). Precipitation records maintained by the Bangladesh Meteorological Department (BMD) and the Bangladesh Water Development Board (BWDB) indicated that a 53-year record had been broken. The previous record was 326 mm on 13 July 1956 (SPARRSO 2010). Hereafter, the term rainfall is used as shorthand for precipitation.

Although the 28 July 2009 event occurred because of a combination of a monsoonal front and a depression in the Bay of Bengal (SPARRSO 2010), recent records of comparable-magnitude events appeared to have occurred exclusively near large cities (341 mm of rain in 24 h on 14 September 2004 in Dhaka and 425 mm of rain in 24 h on 11 June 2007 in the second largest city, Chittagong). Given that Bangladesh has a fairly comprehensive monitoring network of rainfall across the largely rural and agricultural country (254 daily recording stations since 1950; **Figure 3**), the possibility of land use change (such as urbanization) having played a role in precipitation, runoff generation, and groundwater recharge modification deserves a careful look. For a historical trend of land use change since the beginning of Dhaka City in AD 1600, the reader is referred to the left panel of **Figure 1(b)**. A question that has never been asked by water policy planners and scientists alike is *Does the urbanization of Dhaka city over the past 20 years in a largely rural–agricultural surrounding have any detectable effect on local and regional precipitation and runoff patterns?*

The above question is timely for a number of reasons. Dhaka is the fastest growing megacity in the world with an urban population now close to 14 million (World Bank 2010).

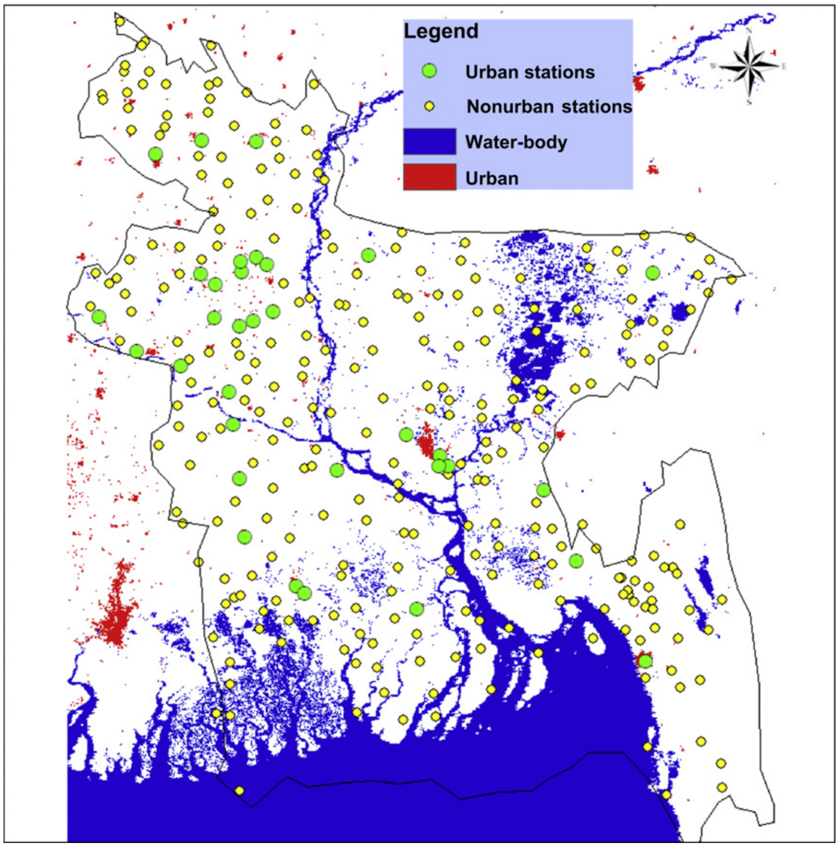

Figure 3 Location of the 254 daily recording rainfall stations from the BMD and BWDB network. Colors green and yellow classify stations as 'urban' and 'nonurban,' respectively, according to MODIS land use classification data.

By 2015, the United Nations (UN) predicts that Dhaka's population will exceed that of Mexico City, Beijing, or Shanghai (Table 1; United Nations 2001). Such a growth rate adds tremendous pressures on the city's renewable but finite water resources for domestic consumption. With ground water table decreasing at the rate of 2–3 m year^{-1} (Rahman and Hossain 2008) and the recharge zone of the deep aquifers of Dhaka (that supply 80% of the city's safe drinking water) becoming progressively encroached, sustainable water resources development is already a challenging task. The encroachment of pervious area or natural wetlands by unplanned urbanization can be appreciated in Figure 4, in which two LANDSAT images

Table 1 Population and growth rate of some of Asian megacities (UN, 2001)

Megacity	*Population (millions)*	*Annual growth rate (2005–2015) (%)*
Dhaka, Bangladesh	12.6	3.2
Shanghai, China	12.7	1.1
Calcutta, India	14.3	2.0
Jakarta, Indonesia	13.2	2.7
Delhi, India	15.3	2.2
Mumbai, India	18.3	2.2

taken a decade apart show drastic changes in the spatial extent of natural water bodies. The large-scale arsenic contamination of shallow but the more abundant ground water available in the rest of the country (Hossain and Sivakumar 2006) makes the dependence on a single source of water (such as the deep aquifers of Dhaka) a risky option for the future. Other sources, such as surface water resources, therefore need to be explored. It is for this reason that the Bangladesh Government has recently started to explore the viability of withdrawing the polluted river waters around Dhaka city as a mitigating source for the dwindling supply of ground water (Rahman and Hossain 2008).

If surface water is to be assessed of its future potential, the impact of changing trends on rainfall and runoff generation (owing to rainfall partitioning and land use patterns) needs to be understood. Climate projections according to the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report (AR4) indicate that the humid regions of South Asia would be significantly altered in terms of rainfall patterns later in the century (Schneider et al. 2007). If such climate projection is to be believed, then the long-term planning for adaptation must consider the local-to-regional feedbacks between the atmosphere and urbanizing land surface. Such a more 'local' approach can be considered more robust as part of the recently coined 'bottom-up vulnerability' assessment approach of a resource in a changing climate (Pielke et al. 2011). In line with previous arguments articulated by Pielke et al. (2009), this vulnerability concept requires the determination of the climatic threats to a resource (such as water), as well as from other socioeconomic and environmental issues. The relative risk from natural and man-made climate variability and longer-term change is then compared with other risks for adopting the optimal mitigation/adaptation strategy. Hossain et al. (2011) argue that the advantage of this bottom-up vulnerability strategy, which must consider the local-to-regional climate feedbacks, is that even if the forecast of water availability because of model projections or other threats were wrong years later, the optimal adaptation strategy identified from multiple threats should have allowed for this error during planning.

Although Bangladesh has an intricate network of rivers, surface water withdrawal from adjacent rivers is not an immediately viable option for Dhaka city because of high levels of industrial pollution from unregulated waste disposal (Kamal et al. 1999). On the other hand, the rainfall and the generated urban runoff (for artificial recharge) around Dhaka city may be a more cost-effective option for water harvesting given the successful experience of more advanced cities faced with perennial water scarcity. For example, the Seletar–Bedok stormwater harvesting scheme in Singapore is an urban runoff capturing system, in which almost one-quarter of the

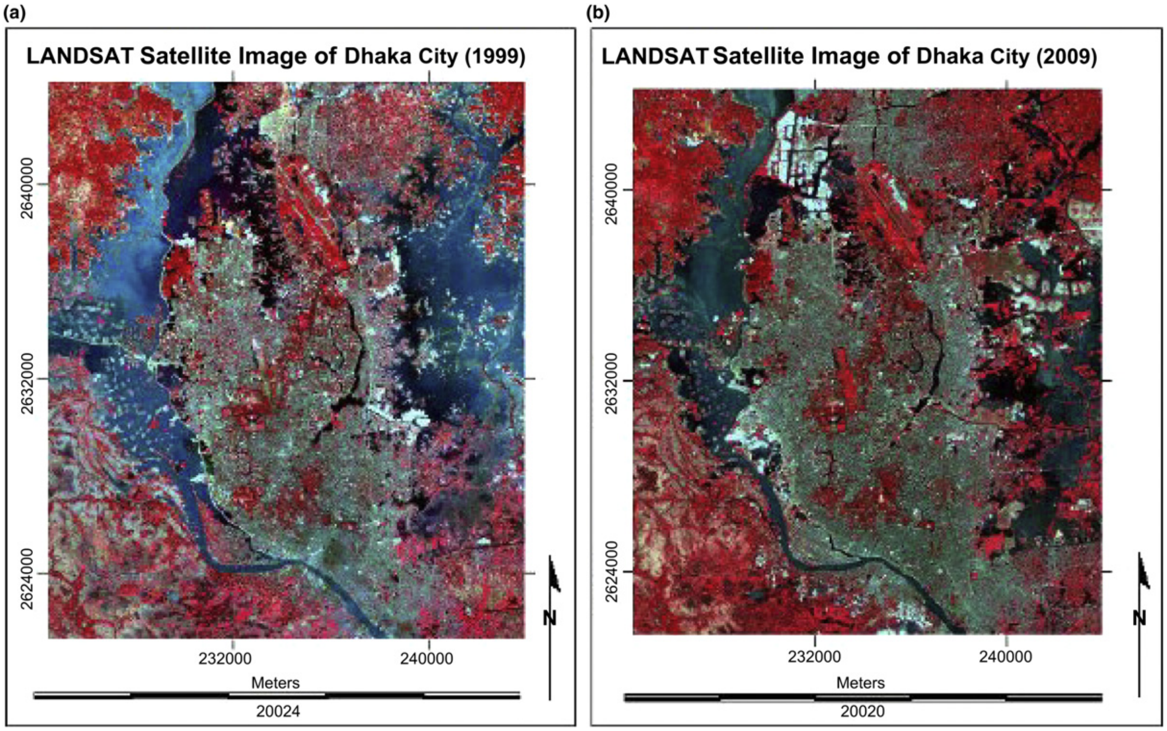

Figure 4 Rapid urbanization and encroachment of pervious area and natural wetlands around Dhaka City as evidenced from LANDSAT images taken during 1999 (a) and 2009 (b).

catchment is in urban area with high rise buildings and impervious surfaces (PUB 2011). The urban runoff generated during storms is directed to a nearby reservoir where it is treated for redistribution through Singapore's drinking water network. If the sustainability of such an urban runoff/rainfall harvesting system is to be explored, rainfall and runoff patterns around Dhaka city needs to be identified in the context of rapid land use change.

There is now considerable evidence suggesting that urbanization can modify rainfall patterns due to a combination of factors (see Mahmood et al. (2009); Shepherd et al. (2010a) for comprehensive reviews), such as (1) increase in cloud condensation nuclei (CCN) concentrations (Ashworth 1929; Rosenfield et al. 2008), (2) changes in surface roughness and low-level convergence (Avissar and Pielke 1989; Shepherd et al. 2010b), or (3) urban heating and land use changes (Bornstein and Lin 2000; Shem and Shepherd 2009). Such changes, independently or synergistically, alter fundamental processes associated with precipitation formation or enhancement (i.e., sensible and latent heat fluxes, convergent flow, cloud water development, and direct thermal circulation patterns).

For example, observational evidence spanning a decade of rainfall measurements indicates that rapid urbanization in the Pearl River Delta of China has reduced precipitation (Kaufmann et al. 2007). However, this study only included urban land cover and no aerosol forcing, which has been shown to suppress precipitation (Rosenfield et al. 2008). A follow-up study reported that the reduction in precipitation was more during the winter season (Seto and Kaufmann 2009). Kishtawal et al. (2009), in a study over the Indian region, found that the frequency of heavy precipitation had actually increased near areas of urbanization. A very recent series of studies by Mitra et al. (2011) has examined changes in premonsoon rainfall in a region near Dhaka city, specifically Kolkata in India. They found evidence that rainfall in the urban observation stations of Kolkata had statistically significant increases over the past 50 or so years, whereas rural stations, the east Gangetic region, and the country itself exhibited no such trends. Lei et al. (2008) found evidence that urbanization in Mumbai, India, contributed to a heavy rainfall event on 26 July 2005. Recent papers by Shem and Shepherd (2009) and Niyogi et al. (2011) have further confirmed that urban land cover can enhance existing convective precipitation systems. Recent studies (such as Molders and Olson 2004; Shem and Shepherd 2009; Shepherd et al. 2010a,b; Niyogi et al. 2011) provide a comprehensive review of the literature on the role of urbanization on the rainfall process and establish that such observations are prevalent in many different geographic, climatic, and seasonal regimes. These studies report the considerable debate on the underlying causes and whether urbanization categorically increases or decreases the intensity and frequency of rainfall. However, most studies agree that under the right circumstances, the urbanization signature on rainfall is detectable.

Regardless of urbanization having a direct impact on the ambient meteorological process of rainfall generation, the study of rainfall patterns in an urban setting is important for sustainable water resources planning because of the urban runoff generation potential of heavy storms. For example, Ntelekos et al. (2007) reported a close relationship between major flash flooding and heavy thunderstorms for Baltimore city (USA) where high urban runoff generation potential was found to be the key factor in overwhelming storm drainage systems. In the study of the recent disastrous flood of Atlanta (in Georgia, USA) in September 2009, Shepherd et al. (2011) found some evidence that urban land cover interactions could have influenced the distribution of the heaviest rainfall and consequential high urban flooding around the city. The frequent urban flooding that is expected to become more frequent and flashier with increasing urbanization is rarely viewed as a 'resource' to mitigate water supply shortage. It seems that only the very advanced cities faced with a historical shortage of water have infrastructure in place to treat urban runoff as a 'resource.' For example, in Singapore, there are several urban runoff capturing reservoirs such as the Seletar–Bedok system (alluded earlier) under construction that aim to convert one-third of Singapore's total area as catchment for urban runoff and reuse, thereby reducing its future dependence on neighboring Malaysia for importing water (PUB 2011).

This study is motivated by the need to assess the water resources vulnerability of the Asian megacity of Dhaka in Bangladesh faced with challenges from climate and socioeconomic pressures. Toward this assessment, the study investigates the rainfall patterns and surface runoff generation potential around Dhaka city in the context of rapid urbanization, which can be viewed as a potential forcing for climate (modification of rainfall process in the atmosphere) and hydrology (modification of runoff transformation on the surface). There are three parts to the study: (1) long-term statistical analysis of rainfall in urban and nonurban regions of Bangladesh to understand the baseline behavior of the greater region, (2) dissection of the weather patterns around Dhaka City during the 28 July 2009 storm event, and (3) rainfall runoff simulations to estimate the potential for harvesting urban runoff from rainfall.

5.25.2 Twenty-Year Analysis of Rainfall Patterns in Urban and Nonurban Regions of Bangladesh

Using daily rainfall records from 254 locations in Bangladesh, the first part of this study investigated the statistical difference between the historical patterns in urban and nonurban regions. The station locations pertained to the combined monitoring network of BMD and BWDB and are shown in Figure 3. Land use/land cover data were obtained from Moderate Resolution Imaging Spectroradiometer (MODIS) Land Cover Type product (Friedl et al., 2002). In this case, the 14-class University of Maryland Classification was used. Accordingly, a binary 'urban' and 'nonurban' classification of the Bangladesh land surface was made. The rainfall monitoring stations located inside an urban area were selected as 'urban' stations, whereas the rest of the stations were classified as 'nonurban'. A total of 24 stations were classified as 'urban' and 230 stations as 'nonurban' using the binary MODIS-based land use classification. Rainfall record for each station spanned 20 years from the mid-1980s to the mid-2000s.

Rainfall histograms were created for four categories: urban monsoon, nonurban monsoon, urban all season, and nonurban all season. From these histograms, the percentiles for the mean, 90% (P90), 95% (P95), and 99% (P99) nonexceedance probability were derived for unconditional and conditional cases (Tables 2(a) and 2(b)). The conditional case (considering only the nonzero rainfall data) is expected to remove the effect of long dry spells during winter months that can mask an underlying trend in the extreme percentiles. Because most of the heavy thunderstorms or 'norwesters' occur during the spring season before the onset of the monsoon season (known locally as 'kalbaisakhi') (IMD Report 1941; Weston 1972), conditional analysis was also carried out for the April–June period (Table 2(c)). This analysis is consistent with the rationale of Mitra et al. (2011), who conducted a similar analysis for Kolkata (in India).

The percentile values reported in Tables 2(a)–(c) indicate that, in all cases (monsoon, all season, and spring), nonurban rainfall is statistically larger than urban rainfall. In order to explore a possible impact on occurrence of heavy rain, analysis was also carried out to observe the effect on frequency of rainfall. The analysis was broken down for heavy events that registered more than 20 mm day^{-1} of rain. Figure 5 confirms that on average, in Bangladesh, nonurban regions experience more days of rainfall than urban regions. Overall, observational data indicate a general suppression of all types of rainfall events in terms of both intensity and frequency in urban regions of Bangladesh.

Although the results appear to agree with a similar study carried out by Kaufmann et al. (2007), where they report for the Pearl River Delta that "This reduction may be caused by changes in surface hydrology that extend beyond the urban heat island effect and energy-related aerosol emissions," there a number of unresolved issues to keep in mind for this study. The presence of particulate matter in air of size less than 10 μm that suppress rainfall and are likely to be present in industrializing environments, was not considered by Kaufmann et al. (2007). In Bangladesh, brick kilns, located in close proximity to urban regions, operate from October–April to supply bricks for the construction season. These kilns have been found to be the major contributor of fine particulate matter in the major metropolitan areas of Bangladesh (Guttikunda 2009). On the other hand, Kishtawal et al. (2009), among others, found a strong relationship between urbanization and heavy rain events, where the impact was usually observed 25–100 km downwind. Hence, a more complete analysis, which is beyond the scope of this study, would require clustering rainfall stations as 'urban' based on a 25- to 100-km downwind proximity to a city rather than on land use alone.

Table 2a Statistical summary of rainfall histogram both for urban and nonurban regions for the unconditional case (where rainfall $\geq$ 0.0 mm day^{-1})

	Precipitation (mm day^{-1}) – all days (unconditional)				
	Mean	*Std. Deviation*	*P90*	*P95*	*P99*
Urban (All season)	5.67	17.30	12.75	29.50	78.84
Nonurban (All season)	7.04	20.00	17.54	36.19	91.67
Urban (Monsoon)	11.92	23.78	31.35	51.98	107.92
Nonurban(Monsoon)	14.47	27.18	37.22	60.79	115.50

Table 2b Statistical summary for rainfall percentiles of the urban and nonurban regions for the conditional case (where rainfall $>$ 0.0 mm day^{-1})

	Precipitation (mm day^{-1}): rain days (Conditional)				
	Mean	*Std. deviation*	*P90*	*P95*	*P99*
Urban (monsoon)	21.59	28.55	48.83	71.95	133.33
Nonurban (monsoon)	25.24	31.88	55.49	81.11	154.68
Urban (All season)	20.82	28.00	46.12	68.04	130.24
Nonurban (all season)	24.61	31.06	53.65	77.88	146.05

Table 2c Same as **Table 2b** but for April–June (conditional case)

	Precipitation (mm day^{-1}) (April–June)				
	Mean	*Std. deviation*	*P90*	*P95*	*P99*
Urban	20.55	23.66	43.22	59.25	104.29
Nonurban	24.06	28.17	49.5	69.55	125.00

Another point to consider is the presence of irrigation, which may play a defining role on modifying precipitation patterns. Bangladesh initiated its green revolution for rice production in the late 1970s through massive expansion of groundwater and surface water irrigation schemes in order to allow three major crop growing seasons a year. A study supporting this point was carried out by Lohar and Pal (1995) to understand the effect of irrigation on premonsoonal rainfall over South West Bengal. They concluded that irrigation reduced the low-level moisture and increased soil moisture. They hypothesized that these processes decreased the intensity of sea breeze circulation and related convection. Therefore, the perennially ponded paddy fields may explain to a large extent the statistical difference between the rainfall percentiles for nonurban and urban regions.

5.25.3 Analysis of the 28 July 2009 Storm Event

According to the Bangladesh Space Research and Remote Sensing Organization (SPARRSO) annual report published in 2010, the 28 July 2009 storm had its genesis in the Bay of Bengal. An area of low pressure formed in the Bay of Bengal on 26 July 2009 that gradually transformed to a fully developed low on 27 July. This then intensified into a depression and subsequently moved to Dhaka City along the northeastern direction producing very heavy rainfall over Dhaka and surrounding regions (SPARRSO 2010). To closely scrutinize the makeup of the storm and understand the possible signature of urbanization, atmospheric reanalysis data was derived from the Modern Era Retrospective-Analysis for Research and Applications (MERRA). The surface sensible heat and latent heat and specific humidity were derived at the level of 850 hPa for the date of the storm. The accumulated rainfall for the same date was acquired using the Tropical Rainfall Measuring Mission (TRMM) Multisatellite Precipitation Analysis (TMPA)

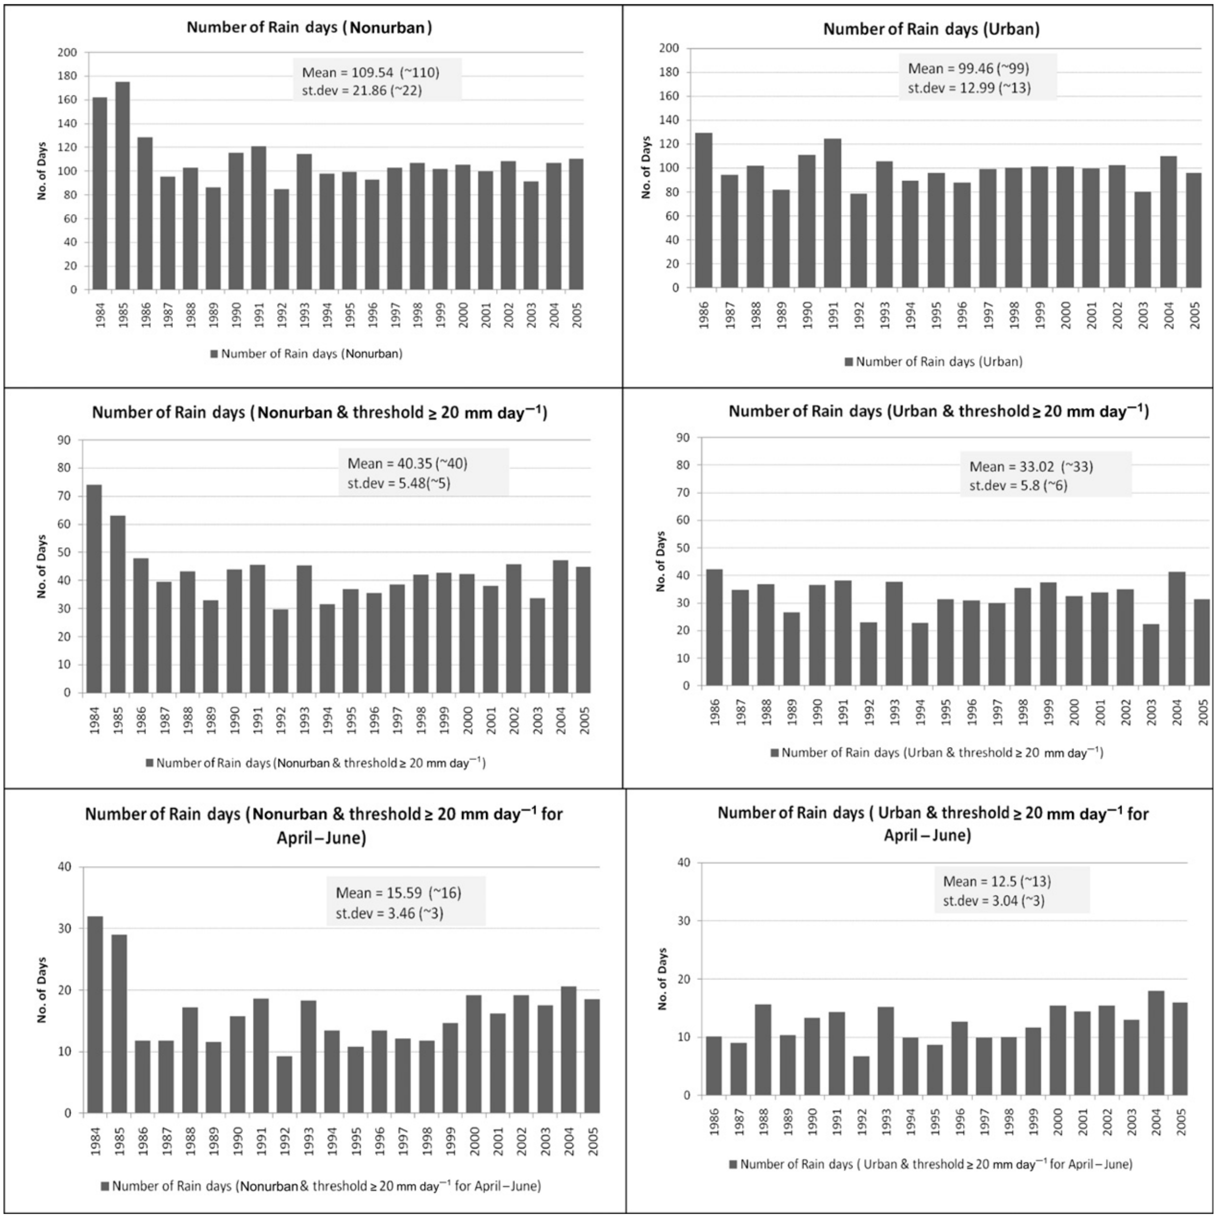

Figure 5 Rainfall frequency analysis for urban and nonurban regions of Bangladesh. Frequency is shown here as the number of rainy days per year for each year. (a) Nonurban and (b) urban. Lowermost panel shows frequency for rain events greater than 20 mm day^{-1}.

(Huffman et al. 2009). The resolution of the data ranged between 0.25 and 1.25°.

Generally, a decrease in sensible heat with a corresponding increase in latent heat and specific humidity is observed from west to east (Figure 6). Although urbanization is expected to result in increased (decreased) sensible heat (latent heat), the resolution of MERRA data is very coarse to attribute any specific change to Dhaka City. The systematic increase of specific humidity along the northeastern direction is indicative of the underlying synoptic condition where monsoonal winds during the months of July–August flow over Bangladesh in the northeaster direction and collide with the mountains in Assam (India).

In order to identify the prevalent wind direction on 28 July 2009 and the historical wind rose diagram, the daily average of eastward and northward wind speed values at 850 hPa were used to determine the direction of wind (Figure 7). For the historical wind rose diagram for July, wind speed data spanning 5 years were used to create the probabilistic map of wind direction and speed using Dhaka city as the center. As expected, historical wind direction and the prevalent wind direction (on 28 July 2009) are found to be in the northeast direction. Using this direction, a group of 10 (eight) rainfall stations was identified as upwind (downwind) of Dhaka city (Table 3). The percentiles (P90, P95, and P99, and the mean) were calculated for the upwind and downwind stations using the 20-year

record of data (Table 4). On an average, it seems the downwind region east of Dhaka city receives about 4 mm more of rainfall a day than its upwind counterpart, which is consistent with historical and contemporary studies (Mote et al. 2007).

Although downwind rainfall is found to be higher for Dhaka city, any physical and direct attribution to urbanization for the 28 July 2009 storm cannot be made given the prevalent condition of a depression in the Bay of Bengal that lasted a few days. For such a land-falling low-pressure system, regions further along the wind direction (such as downwind region east of Dhaka) are naturally expected to experience more rainfall. Lei et al. (2008) studied the catastrophic storm of 26 July 2005 in Mumbai (India) that had similar background synoptic conditions as the 28 July 2009 storm in Dhaka. Using atmospheric modeling, they reported that urbanization potentially contributed to local heavy precipitation at local hotspots and mesoscale precipitation distribution over the Indian monsoon region. Although the urban effect by itself was not found dominant, urbanization appeared to have created conditions that sustained the convergence zone over Mumbai during the duration of the storm.

5.25.4 Assessment of Urban Runoff Generation Potential

In order to understand the ballpark surface water availability from urban runoff generation, a curve number (CN) model was set up to estimate the rainfall partitioning as runoff and recharge/storage. A spatially distributed CN map was first created using high-resolution maps on land use (from LANDSAT) and soils (from Food and Agricultural Organization) at 500 m × 500 m resolution (Figures 8(a) and 8(b)). These two maps were overlaid to derive the CN for each 500 m × 500 m grid box over Dhaka city. There were a total of 1522 grid boxes. A Thiessen polygon map was generated using four rainfall stations near Dhaka city (Figure 8c). The CNs were then lumped as one value (area-weighted composite) for each of the

four Thiessen polygon representative areas of Dhaka city shown in Figure 9. The four rainfall stations were Kaliganj, Dhaka, Savar, and Joydebpur. The preceding 5-day rainfall total was used to determine the antecedent moisture condition (AMC) for each day as I (dry), II (moderately wet), or III (very wet) following the method outlined in Chow et al. (1988) and summarized in Table 5.

The interesting picture that is revealed from this CN-based runoff analysis is that, on an average, about 62% of rainfall usually transforms as runoff and eventually drains into the peripheral rivers of Dhaka as an 'untapped' resource (Table 6(a)). The remaining 38% of rainfall may be considered as a combination of 'recharge,' evaporative losses, and temporary storage. Measurements of groundwater table in Dhaka city

indicate that the table is declining at the rate of 2–3 m year^{-1}, indicating that the uptake is not sustainable in comparison to natural recharge rates (Rahman and Hossain 2008). On the other hand, for a heavy storm, such as on 28 July 2009, more than 95% of the rainfall transforms as surface runoff and eventually drains into rivers and water bodies (Table 6(b)). If the rainfall and the urban runoff from moderate-to-heavy storms could be harvested, it could provide Dhaka with an alternate supply of water to relieve the pressure on its dwindling and renewable water resources.

5.25.5 Discussion

What could be the strategy for future water resources planning based on the above vulnerability assessment in the context of rapid urbanization? There are two key findings that can be used to promote sustainable use of water resources for a megacity such as Dhaka. First, rainfall has a spatial gradient where the downwind region seems to receive statistically higher rainfall than the upwind region. Although such a spatial pattern cannot yet be physically attributed to rapid urbanization, the observation itself has merit for policy planners. Second, urban regions around Bangladesh in general receive less rainfall than the nonurban regions. At the current state of urbanization for Dhaka city, approximately 62% of the rainfall is available as urban runoff, which currently is untapped as a potential mitigating source.

Such a preliminary assessment of urban runoff points to the feasibility of a Seletar-Bedok-type urban runoff harvesting reservoir as in Singapore for supplementing the traditional aquifer-based water supply. At the current growth rate, water demand for Dhaka city is expected to reach 3.2 million m^3 per day (Mm^3/day), or 3200 million l day^{-1}, by 2025 (Figure 10). According to the CN-based runoff assessment shown in Table 5, the long-term daily runoff generation potential for Dhaka city is around 3.06 Mm^3 day^{-1}. Assuming a 50% urban runoff capture efficiency for a runoff harvesting reservoir, about 0.7 Mm^3 day^{-1} of this urban runoff may be used for artificial recharge to systematically raise the groundwater table. The remaining 0.8 Mm^3 day^{-1} amount could be treated for suspended solids removal and then used for nondrinking consumption. Such a conjunctive approach would not only relieve pressure on the deep aquifers, but also gradually counter the declining groundwater table and build strategic storage for use later in the century. For the heavy storms, more than 90% of the rainfall is generated as runoff. This indicates that rainwater harvesting should be promoted in the downwind regions located east of Dhaka city and transported back for urban consumption as drinking water through bottling or a network of pumping stations and pipe networks.

A recent pilot-scale study implemented by the Bangladesh Institute of Water Modeling (IWM) for Dhaka Water Supply and Sewerage Authority (DWSSA) during 2011 indicated that rainfall and runoff harvesting can indeed be successful in cost-effective recharge of ground water by using injection well by gravity (IWM 2011). In fact, this pilot-scale study demonstrated that if *60% of the total rainfall from concrete roof tops of the city area can be harvested then annually about 89,496 millions of liters rain water will be available for artificial recharge to aquifer…can make*

245 million liters per day for city water supply. Such an endorsement of our vulnerability assessment approach through an independent pilot-scale study (i.e., earlier we claimed in our study that about 62% of rainfall is potentially an untapped resource for Dhaka) demonstrates the effectiveness of the bottom-up approach as a decision-making tool for the adaptation community. Overall, this study demonstrates that an accurate understanding of the rainfall and runoff modification patterns in the context of rapid land use change (such as urbanization) using a bottom-up assessment approach is critical to forecasting future water resources vulnerability and for designing harvesting schemes.

5.25.6 Conclusion

This study explored the water resources vulnerability for Dhaka city in the context of rapid land use change that compromises the sustainability of its renewable water resources. Using observational evidence, it found that rainfall experienced strong spatial signature, where the region downwind of the city seemed to receive statistically higher rainfall than the upwind region. Direct physical attribution to rapid urbanization of Dhaka city was not possible for the 28 July 2009 storm that broke a 53-year record. In the wider context of the country, the study also found that urban regions in general receive less rainfall than the nonurban regions.

As a future extension of this study to pinpoint more specifically the plan for sustainable water resources development, atmospheric modeling combined with investigation of local convective initiation should be carried out. Such a study would help policy planners understand if future urbanization may alter the frequency and intensity of heavy rainfall events in the context of a changing climate. The CN model used for urban runoff in this study provides only an external description of water availability (e.g., Dhaka city as the control volume). More sophisticated models for urban runoff such as Storm Water Management Model (SWMM) or MIKE-URBAN could be used for detailed planning in the near future. Such models take into account the topography and urban drainage network consisting of pipes and open channels and, provide, as a decision-making output, optimal locations for capture of runoff. Such modeled locations can be potential feasibility sites for the Selatar-Bedok-type urban runoff capturing reservoir or for artificial recharge of groundwater. Although this study shows promise for a sustainable water resources development plan for Dhaka city, it is only with such detailed models and further analysis that the design specifications of systems be identified to safeguard the water security of South Asian megacities such as Dhaka.

Acknowledgments

Partial support for this study was received from the Center for Management Utilization and Protection of Water Resources at Tennessee Technological University (TTU) and NASA New Investigator Award (NNX08AR32G) to Faisal Hossain. Ahmed Degu was supported by the TTU Diversity Fellowship (2010–2013). Rainfall and land use data for Bangladesh were available as part of a 5-year Memorandum of Understanding (MOU) between Institute of Water Modeling and TTU. The study also benefited from the NASA Precipitation Measurement Grant of Marshall Shepherd.

INDEX

Notes

Abbreviations used in subentries are defined as main entries

Cross-reference terms in italics are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to the end of each article for additional cross-references - not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of heading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by t and f refer to tables and figures respectively. vs. indicates a comparison.

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization. For example, 'databases' is alphabetized before 'data collection'. Prefixes and terms in parentheses are excluded from the initial alphabetization.

Where index subentries and sub-subentries pertaining to a subject have the same page number, they have been listed to indicate the comprehensiveness of the text.
